These debates raise questions about the strength of the argument against the reality of color. Consider the passage from S. E. Palmer, quoted in the first section. It is possible to see it as presenting an argument against the reality of colors. It takes the form: when objects are seen as colored, the objects are experienced in certain ways, they are seen as having certain qualities, but the objects do not have those qualities; the colors perceived are different from any the physical objects possess. There are two claims implicit here: (i) the colors objects are perceived as having – the “apparent colors” – a certain distinctive character, and (ii) the physical sciences have shown that no qualities with that particular character play any causal part in the perception of colors. From this, it is concluded that neither objects nor lights are colored in anything like the way they are experienced.

This argument depends on one’s being able to characterize the distinctive character of the “apparent colors.” Here is an important point on which philosophers divide. One group holds that it is obvious that this distinctive character includes a qualitative aspect, one that is familiar to common perceivers. It is by virtue of having this qualitative character that the various colors fit together collectively, in system of relationships of similarities and differences (a psychological color space). In this system, for example, orange is between red and yellow, resembling each, whereas it is not between blue and green, nor blue and red. Another group of philosophers, however, holds that any such qualitative aspect is no part of colors themselves, where the colors are the properties one’s experiences *represent* objects as having. (It may be part of the way colors are represented, rather than essential to the color itself. Think here of the difference between *heat* in a body and *the way things are experienced* as hot or cold.) The claim may be put as follows: (1) colors are certain properties, ones that objects look to have (appear to have) when one sees the objects; (2) the properties objects look to have are the qualities one’s experiences *represent* the objects as having.

Everything now turns on what theory of *representation* one can call upon. Once again opinions (“carefully considered positions”) differ. On one view, the qualities are ones that play the appropriate causal role in the production of the experiences of color. As a consequence, so it is argued, these qualities are ones that it requires scientific inquiry to locate. Accordingly, it is thought there are good reasons to think that surface colors of objects, for example, are spectral reflectances. On the other hand, another group of philosophers reject that theory of representation, arguing that the qualities represented are dispositional properties: dispositions to cause experiences of the right type.

Then again, there are other philosophers who defend a different version of color realism. They accept that the colors do have the relevant qualitative character, but deny that the scientists provide good argument against the reality of color. That is to say, they accept that the ordinary conception of color is of features with a simple,

qualitative character, one that is typically revealed in color perception, but they deny that the scientific argument against the reality of such qualities is cogent. Contemporary defenders of this view appeal to the claim that colors are qualities that are supervenient on light-modifying features of physical bodies. The light-modifying features cause visual experiences, but, so it is argued, colors are qualities that are revealed in experience.

There is another argument against color realism, which has a long pedigree, but which has come to prominence in recent times. One of its strongest advocates has been C. L. Hardin [9]. Any defense of color realism has to acknowledge and defend a distinction between *real color* and (merely) *apparent color* or between *real color* and *illusory color*. Any such distinction, however, needs to rely on a distinction between standard conditions and nonstandard ones and between normal, or standard, observers and nonstandard observers. Things which are *really blue*, say, are ones that will look blue to standard perceivers, in standard conditions. In other sorts of conditions, or to other kinds of perceivers, they may look to have other colors. If so, those other colors will be illusory ones, or “merely apparent” ones.

Hardin has argued that there is no way of identifying such conditions, and such perceivers, that is not arbitrary. A uniformly colored square, for example, will appear differently if the sides are, respectively, 2, 10, and 100 cm. And they will look to have different colors, when set against different backgrounds. The problem is even more pronounced in the case of standard observers. Competent human color perceivers divide into a number of groups that differ, for example, on which hues are instances of the unique hues: unique blue, red, green, and yellow. The differences are quite dramatic. Not only that, but there are significant differences between males and females, with respect to these abilities.

This kind of problem has led some theorists, e.g., Jonathan Cohen, to defend another form of color realism, a version of color relationalism [10]. On this theory, color is a relational property, defined with respect to relations between the object, the environmental viewing conditions, and the kind of perceiver. On this view, there are

no such properties as *blue simpliciter*, *red simpliciter*, etc.; there is only blue-for-perceiver kind A, in conditions C; blue-for-perceiver kind B, in conditions C*; and so on. It should be noted that although Cohen calls the account “realist,” it is a special type of realism. On this account, a whole host of relational properties are equally real.

Color Relationalism

There are other forms of color relationalism which have links to action-based theories of perception, as developed principally by the psychologist J. J. Gibson. A leading example is the theory defended by Evan Thompson, the *Ecological View of Colors*. On this account, colors are taken to be dependent, in part, on the perceiver and so are not intrinsic properties of a perceiver-independent world. Being colored, instead, is construed as a relational property of the environment, connecting the environment with the perceiving animal. In the case of the color of physical surfaces, “being colored corresponds to the surface spectral reflectance as visually perceived by the animal” [11]. Thompson’s work has been supported by that of Alva Noe, who defends what he calls “an enactive approach to perception” [12]. As in the case of Thompson, his theory is guided by Gibson’s work, albeit with modification.

More recently, other forms of relational theories have emerged. Of these one of the most important is the version defended by M. Chirimuuta, in her book, *Outside Color*, 2015 [13]. Chirimuuta advocates a version of color relationalism which she calls *Color Adverbialism*: On this account, colors are not properties of external physical objects, or of brains, or of our mental states; instead, they are properties of perceptual processes or interactions which involve objects, brains, and mental states. So, according to color adverbialism, “seeing the colors” means “seeing in a colourful way.” She appeals to recent research on color vision, relied to the function of color vision, to argue that it provides great difficulties for objectivist color realism – both primitivist and reductionist physicalist. While she admits that anti-realism, especially the

form favored by Hardin, is in a better position, they think that color adverbialism presents the best explanation.

Another important recent contributions to the philosophy of color is the book by Matthen [14]. In this work, Matthen articulates a theory of sense-perception in which color plays a prominent role. The work is significant for the theory of color that he presents, one that draws heavily on comparative studies of color vision among different species. Matthen replaces his earlier objectivist views on color by an account that has more in common with the ecological theory favored by Thompson.

Goethe's *Theory of Colors*

This entry would not be complete without reference to the color theory of the famous German author Johann Wolfgang von Goethe. Goethe was deeply critical of Newton's analytical approach and of his theoretical explanations of color phenomena [15]. While mainstream color science has been mostly dismissive of Goethe's attack, there are thinkers who find a positive side to Goethe's work.

There are two aspects to Goethe's critique. One is that he describes experiments that, he claims, contradict Newton's theory. The second aspect is that he provides a set of observations that Newton's theory does not, and cannot, explain. Additionally, he claims to provide an alternative explanation for these phenomena. H. Helmholtz, the nineteenth-century physicist and color scientist, rejected the criticisms of Newton's science as based on serious misconceptions [16]. First of all, Newton was well aware of some of the experiments described, and, more importantly, all of these experiments can be satisfactorily handled by Newton's theoretical approach. With respect to the other observations, it is true that Newton does not explain them, but these phenomena are not ones that his theory is designed to explain. Nevertheless, Helmholtz praised Goethe's descriptions, of both the experiments and the other observations, as accurate and important.

The issues are perhaps best brought out by a response to Goethe's work, by the philosopher L. Wittgenstein [17]. For a clear exposition, see an article by another philosopher, Zeno Vendler [18]. Wittgenstein points out that Goethe, despite what he thinks, does not provide a scientific theory at all; his activity has a different nature. What he is doing is better described as providing phenomenological observations, i.e., observations of how colored objects appear and of the relations between those appearances, e.g., that yellow (of the fullest saturation) is lighter than red. The resulting propositions that emerge from this sort of activity are not ones that Newton's theory is designed to address, but they are very important, nevertheless. (Whether they can be explained by Newton's theory supplemented by neuroscience is not so easily decided.)

Definition

Phosphor (fluorescent powder) is a kind of inorganic materials which absorbs the energy from electrons, photons, or even other forms of microscopic particles and converts it into visible light. Phosphor (fluorescent powder) has a history of

about 100 years and today plays one of the key roles in lighting, display, and imaging. So far there are varieties of phosphors finding their applications in cathode-ray tubes (CRTs), fluorescent lamps, x-ray films, plasma display panels (PDPs), and recently developed white light-emitting diodes (w-LEDs).

The Mechanism of Luminescence

Although phosphors are available in diversity, the mechanisms of luminescence in them are similar, including the following primary items:

- Transitions of rare-earth ions and transition metal ions
- Crystal field splitting and nephelauxetic effect
- Energy transfer

Transitions of Rare-Earth Ions and Transition Metal Ions

Essentially, luminescence of phosphors is a process of electron transitions, which occurs in luminescence center ions (active centers). But not all of the ions can be considered to act as optically active centers, which are usually based on rare-earth ions or transition metal ions. In this section, we will concentrate on these luminescent centers and discuss their energy levels.

Electronic Configuration, Energy Levels, and Transitions of Rare-Earth Ions

The rare-earth ions usually refer to lanthanide ions, Sc^{3+} and Y^{3+} . The electronic configurations of both trivalent and divalent rare-earth ions in the ground states are shown in Table 1. It can be seen that the 4f orbit is empty for Sc^{3+} , Y^{3+} , and La^{3+} and fully filled for Lu^{3+} , which will lead to no luminescence due to lack of energy levels generated by unpaired 4f electrons, while the lanthanide ions from Ce^{3+} to Yb^{3+} have partially filled 4f orbitals, thus they exhibit their characteristic energy levels, which can induce luminescence processes. Additionally, there are three divalent lanthanide ions, Sm^{2+} , Eu^{2+} , and Yb^{2+} , and their electronic configurations are the same as those of

Phosphors and Fluorescent Powders, Table 1 Electronic configurations and ground state of rare-earth ions

Ions	4f electrons	Ground state	Ions	4f electrons	Ground state
Sc ³⁺	0	¹ S ₀

Lu ³⁺	14	¹ S ₀			

Eu³⁺, Gd³⁺, and Lu³⁺, respectively. The electronic state is denoted as ^{2S+1}L_J, where S, L, and J are the spin angular momentum, orbital angular momentum, and total angular momentum, respectively.

The experimentally measured energy levels of trivalent lanthanide ions in lanthanum fluoride (LaF₃) are illustrated in *Dieke diagram* (as shown in Fig. 1). It presents the energy of electronic states ^{2S+1}L_J for trivalent ions in LaF₃ and almost any other crystals. The number of levels is determined by the ion species and degree of energy level degeneracy, which can be influenced by the symmetry of the crystal field surrounding the lanthanide ions, and the width of each level is a reflection of the crystal field splitting. By taking advantage of the *Dieke diagram*, one can explain the absorption and emission spectra and identify each spectral peak of rare-earth ions in different luminescent materials. Especially, the luminescence of trivalent rare-earth ions with f-f transitions can be assigned according to *Dieke diagram*. An other group of rare-earth ions, represented by Ce³⁺ and Eu²⁺ with f-d transitions, deserve much more attentions for their higher luminescent efficiency, which will be discussed as following.

Ce³⁺: The Ce³⁺ ion has the simplest electron configuration among the rare-earth ions. The 4f¹ ground-state configuration is divided into two sublevels, ²F_{5/2} and ²F_{7/2}, and these two sublevels are separated by about 2,000 cm⁻¹ as a result of spin-orbit coupling. This is the reason for the double bands usually observed in the Ce³⁺ emission spectra. The 5d¹ excited state configuration is split into two to five components by the crystal field, with the splitting number depending on the crystal field symmetry. The Ce³⁺ emission is strongly affected by the host lattice through the crystal field splitting of the 5d orbital and the nephelauxetic effect and usually covers the visible light region.

Eu²⁺: The Eu²⁺ ion has the ground state of 4f⁷ (⁸S_{7/2}) and the excited state of 4f⁶5d¹. The luminescence is strongly dependent on the hosts, with the emission color covering ultra-violet to red. The abundant emission colors are due to the different covalency (nephelauxetic effect) and crystal field splitting from one host to another. With large covalency or crystal field splitting, the 5d energy level of Eu²⁺ is lowered greatly, leading to the red shift of the absorption and emission bands.

Transitions of Transition Metal Ions

Transition metal ions are an important class of dopants in luminescent materials and solid-state laser materials, and their emission colors are very abundant. Among the transition metal ions, Mn²⁺ and Mn⁴⁺ are two of the most important and useful luminescent centers in phosphors, which will be discussed below.

Mn²⁺: The emission color of Mn²⁺ always exhibits green or red, depending on the crystal field strength of the host crystal. The emission spectrum of Mn²⁺ displays a broad band, and the emission corresponds to the ⁴T₁ (⁴G) → ⁶A₁ (⁶S) transition. In general, the emission color is green when Mn²⁺ is tetrahedrally coordinated, and it is red when Mn²⁺ is octahedrally coordinated. The absorption of Mn²⁺ is usually low due to the spin-forbidden transition. To improve the absorption of Mn²⁺, energy

This effect is called crystal field effect, which has shown great influence on luminescence ions. Crystal field splitting is, in fact, the energy level splitting of luminescence ions by the influence of crystal field. Generally, the crystal field splitting is affected by symmetry of coordination anions and the distances between luminescence ions and coordination anions. And crystal field splitting is usually described by the point charge electrostatic model (PCEM), which can be usefully applied especially in the case of coordination in the form of an octahedron, cube, tricapped trigonal prism, and cuboctahedron.

Some electrons of the ligands move into the orbitals of the central ion and reduce the cationic valency. Due to this reduction, the d-electron wave functions expand toward the ligands to increase the distances between electrons, reducing the interaction between them. This effect is called the nephelauxetic effect. This effect may be considered to increase with ligands anion in the order: $F^- < O^{2-} < N^{3-} < Cl^- < Br^- < I^- < S^{2-}$.

Energy Transfer

Energy transfer means energy migrating from a higher energy ion to another lower energy ion or even from a host crystal to activators. Thus, three kinds of energy transfer should be included as following:

- *The energy transfer between the same ion species.* When the ionic separation becomes smaller, the energy transfer probabilities increases by means of resonant, exchange interaction, and multipolar interaction. As a result, the optical exciton is trapped at defects or impurity sites, enhancing non-radiative relaxation, which is the reason for concentration quenching.
- *The energy transfer between different ion species* can take place when they have closely matched energy levels. The energy transfer result is that the luminescence of energy-accepted activators enhanced and the luminescence of energy-donated activators weakened. Typically, Ce^{3+} ions transfer energy to Tb^{3+} ions in the phosphors $CeMgAl_{11}O_{19}:Ce^{3+}$, Tb^{3+} ; $LaPO_4:Ce^{3+}, Tb^{3+}$; etc.

- *The energy transfer from a host crystal to activators* mainly refers to energy transfer from an excited oxy-anion complex to lanthanide ions. This kind of energy transfer is commonly seen in vanadate, molybdate, tungstate, etc., such as $YVO_4:Eu^{3+}$, $CaMoO_4:Eu^{3+}$, and $Y_2WO_6:Eu^{3+}$.

Characterization

Besides the mechanism of luminescence, characterization of the prepared phosphors is vital to evaluate the practical application. The principal characterization of phosphors can be listed as the following:

- Spectrum
- Quantum efficiency
- Thermal quenching
- Fluorescent lifetime

Spectrum

When light interacts with a phosphor, refraction, absorption, scattering, and luminescence will occur. The luminescence process – excitation and emission – will be discussed and characterized by excitation and emission spectra.

Emission Spectrum

During the luminescence process, the distribution of emission photon number varies with emission wavelength or frequency, that is, the so-called emission spectrum, which is important to judge what color of light is emitted by the phosphor and to calculate the color coordinates. Generally, two kinds of emission spectrum are presented: line spectrum for activators with f-f transitions and band spectrum for activators with d-electron transitions. No matter what kinds of emission spectrum, it shows difference with activator species and compositions of host.

Excitation Spectrum

The distribution of emission photon number of the monitored wavelength varies with excitation wavelength or frequency. Thus, it, in fact, is a specific emission spectrum, which is used to

characterize the effectiveness of excitation. From this spectrum, it is convenient to judge the effective excitation wavelength for phosphors, which is important for practical use.

Quantum Efficiency

The emission and excitation spectra let people know what light the phosphor emits and the effectiveness of different excitation wavelength, while it still does not know how efficient the energy conversion is. Thus, the quantum efficiency is introduced. The quantum efficiency of a phosphor is how much absorbed light (photons) is converted into emission, which is in the range of 0–1. This is also called internal quantum efficiency. The external quantum efficiency denotes the ratio of the number of photons of the emitted light to that of the incident light on a phosphor. The internal (η_i) and external (η_0) quantum efficiency can be computed by the following equations:

$$\eta_i = \frac{\int \lambda \cdot P(\lambda) d\lambda}{\int \lambda \{E(\lambda) - R(\lambda)\} d\lambda}$$

$$\eta_0 = \frac{\int \lambda \cdot P(\lambda) d\lambda}{\int \lambda \cdot E(\lambda) d\lambda}$$

where $E(\lambda)/h\nu$, $R(\lambda)/h\nu$, and $P(\lambda)/h\nu$ are the number of photons in the spectrum of excitation, reflectance, and emission of the phosphor, respectively.

Thermal Quenching

Thermal quenching of luminescence is the phenomenon in which the luminescence efficiency decreases as the temperature increases due to the increasing phonon–electron interaction. This phenomenon can be explained by configuration coordinate (as shown in Fig. 2). The excited electron can go across the crossing point of ground state and excited state and relax to the ground state non-radiatively, the probabilities of which will increase with the increasing temperature. The

Phosphors and Fluorescent Powders, Fig. 2 Configurational coordinate diagram for thermal quenching

energy difference between the lowest vibrational level of excited state and the crossing point is called activation energy for thermal quenching, which is used to judge the thermal quenching properties of phosphors. The larger value of activation energy means higher energy barrier for thermal quenching. The activation energy can be calculated by the Arrhenius equation:

$$I_T = \frac{I_0}{1 + c \exp\left(\frac{-\Delta E}{kT}\right)}$$

Here I_0 is the initial emission intensity, I_T is the intensity at different temperatures, ΔE is the activation energy of thermal quenching, c is a constant for a certain host, and k is the Boltzmann constant.

Fluorescent Lifetime

Fluorescent lifetime is another important factor, which is not used to judge the phosphors good or bad but limits the applications of phosphors. For display and imaging applications, short fluorescent lifetime is needed as well as high luminescence efficiency and narrow full width at half maximum (FWHM) of emission spectrum. The decay process of the luminescence intensity $I(t)$

after the termination of excitation at $t = 0$ is generally represented by an exponential function of the elapsed time after the excitation:

$$I(t) = I_0 \exp(-t/\alpha)$$

where α is the decay time constant of the emission and $\tau = -1/\alpha$ is named fluorescent lifetime. For convenience, fluorescent lifetime is defined as the duration of $I(t)$ decreasing from I_0 to $1/eI_0$. Generally, light emission due to a forbidden transition has a long fluorescence lifetime, while that due to an allowed transition usually shows a short fluorescence lifetime, but that is not absolute since the electron may be captured by a trap or lattice defect, leading to long after-glow luminescence. Fluorescent lifetime is usually determined by measuring the time-resolved emission spectroscopy, which provides information on crystal structure and the kinetic behavior of luminescent excited states and intermediates as well.

Practical Phosphors

As mentioned above, phosphors are various and have shown varieties of applications in lighting, display, and imaging. However, the lighting industry constitutes the largest consumer of phosphors and produces the largest quantity of phosphor-related products. Thus, the widely used phosphors for fluorescent lamps and w-LEDs are chosen and introduced as following:

- Phosphors for fluorescent lamps
- Phosphors for w-LEDs

Phosphors for Fluorescent Lamps [2]

The invention of fluorescent lamp can be traced back to the nineteenth century while the calcium halophosphate phosphor was developed, and the age of fluorescent lamps was truly entered since 1950s. However, the problems of poor color-rendering and high color temperature of this lamp prompted the development of three-band fluorescent lamp, which shows higher color-rendering and even higher luminescence

efficiency. The practical phosphors for fluorescent lamps will be introduced briefly as the following.

Calcium Halophosphate Phosphors for Traditional Fluorescent Lamps

Crystal structure: These phosphors have an apatite-type structure belonging to the hexagonal system. The Ca^{2+} ions have two different sites: Ca (I) coordinated by six oxygen and Ca (II) coordinated by halogen ions. Sb^{3+} and Mn^{2+} ions are capable of replacing Ca^{2+} ions at both types of sites. In addition, the Ca^{2+} ions are possible to be partially replaced by Sr^{2+} , Ba^{2+} , and Cd^{2+} ions.

Luminescent properties: These series of phosphors are doubly activated by Sb^{3+} and Mn^{2+} . The Sb^{3+} emission peak is located at ~ 480 nm and is not influenced by the kind of halogen in the host. The emission peak of Mn^{2+} is located at 575–585 nm, depending on the F:Cl ratio. Energy transfer from Sb^{3+} to Mn^{2+} can be observed and show great influence on emission colors by turning $\text{Sb}^{3+}:\text{Mn}^{2+}$ ratio. By adjusting appropriate compositions of these phosphors, the color temperatures of the white light can be obtained ranging from 3,000 to 6,500 K. In addition, these series phosphors have almost 90% of the emission intensity retained, even at 200 °C, without a shift in the emission peak.

Phosphors for Three-Band Fluorescent Lamps

Phosphors utilized for three-band lamps can be grouped into three categories as following:

1. Red phosphor: $\text{Y}_2\text{O}_3:\text{Eu}^{3+}$ is the only available red phosphor for three-band lamps mainly due to its nearly perfect luminescence properties, except for the high price.

Crystal structure: The crystal structure of this phosphor is cubic, and Eu^{3+} ions occupy the two Y^{3+} sites of C_2 and S_6 symmetry.

Luminescent properties: The excitation spectrum has a broad band ranging from 200 to 300 nm, which matches perfectly with 254 nm light emitted by mercury vapor. The emission spectra contains a very narrow and intense emission band at 611 nm (originates from the $^5\text{D}_0 \rightarrow ^7\text{F}_2$ transition of Eu^{3+}) with a

full width at half maximum of ~ 7 nm. This phosphor exhibits high color purity, high quantum efficiency (nearly 100%), excellent thermal quenching properties, and stable chemical properties.

2. Green phosphors: There are three kinds of practicable green phosphors being developed successively, which are $\text{CeMgAl}_{11}\text{O}_{19}:\text{Ce}^{3+}, \text{Tb}^{3+}$; $\text{LaPO}_4:\text{Ce}^{3+}, \text{Tb}^{3+}$; and $\text{GdMgB}_5\text{O}_{10}:\text{Ce}^{3+}, \text{Tb}^{3+}$.

Crystal structures: $\text{CeMgAl}_{11}\text{O}_{19}:\text{Ce}^{3+}, \text{Tb}^{3+}$ belongs to the hexagonal system and has the same magnetoplumbite structure as the $\text{PbFe}_{12}\text{O}_{19}$ crystal. $\text{LaPO}_4:\text{Ce}^{3+}, \text{Tb}^{3+}$ belongs to the monazite crystal group. $\text{GdMgB}_5\text{O}_{10}:\text{Ce}^{3+}, \text{Tb}^{3+}$ has monoclinic symmetry and is isostructural with $\text{LaCoB}_5\text{O}_{10}$.

Luminescent properties: The common characteristics of these phosphors are activated by Tb^{3+} and adopting Ce^{3+} as sensitizer, because the absorption lines of Tb^{3+} in the ultraviolet region does not match the light emitted by mercury vapor, but Ce^{3+} can absorb the light emitted by mercury vapor efficiently and transfer the energy to Tb^{3+} with a high efficiency by overlapping the emission spectra of Ce^{3+} and absorption lines of Tb^{3+} . Thus, these phosphors exhibit the emission of Tb^{3+} with emission peak at ~ 543 nm (corresponding to the $^5\text{D}_4 - ^7\text{F}_5$ transition) and a full width at half maximum of ~ 10 nm. But by comparing other properties, the $\text{CeMgAl}_{11}\text{O}_{19}:\text{Ce}^{3+}, \text{Tb}^{3+}$ presents much more excellent in quantum efficiency (as high as 97%), thermal quenching properties, and chemical stability; therefore, the $\text{CeMgAl}_{11}\text{O}_{19}:\text{Ce}^{3+}, \text{Tb}^{3+}$ phosphor is still one of the most important and widely used green phosphors for three-band fluorescent lamps.

3. Blue phosphors: $(\text{Sr}, \text{Ca}, \text{Ba})_5(\text{PO}_4)_3\text{Cl}:\text{Eu}^{2+}$ and $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}^{2+}$ are two main classes of blue-emitting phosphors.

Crystal structures: $(\text{Sr}, \text{Ca}, \text{Ba})_5(\text{PO}_4)_3\text{Cl}:\text{Eu}^{2+}$ has an apatite-type structure belonging to the hexagonal system. $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}^{2+}$ has a crystal structure similar to hexagonal β -alumina.

Luminescent properties: $(\text{Sr}, \text{Ca}, \text{Ba})_5(\text{PO}_4)_3\text{Cl}:\text{Eu}^{2+}$ gives a sharp emission spectrum peaking at 447 nm and a broad band

excitation spectrum covering 200–400 nm region. Partial replacement of Sr^{2+} by Ca^{2+} or Ba^{2+} results in red shift or blue shift, mainly ascribed to the change of crystal field. Incorporation of a small amount of Ba^{2+} serves to improve the degradation characteristics; incorporation of a small amount of borate may increase the emission intensity. $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}^{2+}$ also has a broad band excitation spectrum in the ultraviolet region and an emission band with the peak located at ~ 450 nm. Generally, the luminescent properties can be adjusted by controlling the Al_2O_3 ratio, Eu^{2+} concentration, and Sr^{2+} replacing part of Ba^{2+} . By comparison, $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}^{2+}$ shows higher quantum efficiency (appears to exceed 100% measured by conventional methods). The relative poor thermal quenching properties are still challenges for both blue phosphors.

Phosphors for W-LEDs

W-LEDs are considered to have brought about a revolution in energy-efficient lighting due to the outstanding advantages such as long lifetime, high energy efficiency, and environmental friendliness. Currently, w-LEDs are commonly generated by the combination of the blue LED chips and yellow-emitting phosphors. But, the white light obtained by this approach would result in low color-rendering index and high correlated color temperature due to the red emission deficiency in the visible spectrum. Generally, red-emitting phosphors are added to make up for this deficiency. Thus, the widely used phosphors for w-LEDs can be divided into two groups as the following:

Oxide Yellow Phosphors

1. $\text{YAG}:\text{Ce}^{3+}$ garnet phosphor

Crystal structure: YAG is the abbreviation of $\text{Y}_3\text{Al}_2\text{Al}_3\text{O}_{12}$, which has the classical garnet structure represented by the general formula $A_3B_2X_3\text{O}_{12}$, where A , B , and X are eight, six, and four coordinated with the surrounding O, forming dodecahedron, octahedron, and tetrahedron, respectively. The octahedron and tetrahedron do not share any edge among themselves, but they share edges with at least one dodecahedron.

Luminescent properties: The excitation spectrum of YAG:Ce^{3+} is mainly composed of two broad bands with excitation peaks located at 340 and 460 nm, respectively. The emission spectrum shows a very broad band with emission peak at ~ 535 nm and a full width at half maximum (FWHM) of ~ 100 nm. The high external quantum efficiency (more than 83%), excellent thermal quenching properties (more than 87% of the initial emission intensity remained at 150°C), and the strong absorption of blue light emitted by blue LED chip made YAG:Ce^{3+} one of the most important and widely used phosphors for white LEDs. Actually, YAG:Ce^{3+} is a green-yellow-emitting phosphor, and the emission spectrum in the red region is very weak, which results in the produced white light having a high color temperature. Generally, Gd^{3+} replacing part of Y^{3+} or increasing Ce^{3+} concentration may turn the emission spectrum shift toward longer wavelength, but the quantum efficiency decreases radically; meanwhile, the thermal quenching increases.

2. $\text{Sr}_2\text{SiO}_4\text{:Eu}^{2+}$ silicate phosphor

Orthosilicate phosphor has outstanding advantages such as high luminescence efficiency, low cost, and strong excitation in UV to blue light region, which have attracted lots of attentions.

Crystal structure: Sr_2SiO_4 has two types of crystal structures, which are orthorhombic corresponding to α' phase and monoclinic corresponding to β phase. The α' and β phases of Sr_2SiO_4 are isostructural with Ba_2SiO_4 and $\beta\text{-Ca}_2\text{SiO}_4$, respectively. Generally, in order to stable the $\alpha'\text{-Sr}_2\text{SiO}_4$ phase, Ba^{2+} ions were introduced to replace part of Sr^{2+} ions. For $\alpha'\text{-Sr}_2\text{SiO}_4$, Sr^{2+} ions have two kinds of sites, Sr(1) and Sr(2), coordinated by 10 and 9 oxygen atoms, respectively.

Luminescent properties: The excitation spectrum of $\text{Sr}_2\text{SiO}_4\text{:Eu}^{2+}$ shows a broad band covering the spectral region of 200–550 nm with excitation peak at about 387 nm. The emission spectrum shows two bands centered at about 490 and 560 nm, assigning to the luminescence centers

occupying two types of Sr sites: Sr(1) and Sr(2), respectively. Due to the weak 490 nm emission peak, the emission spectra of $\text{Sr}_2\text{SiO}_4\text{:Eu}^{2+}$ shows emission peak at about 560 nm, which can be shift to longer wavelength by increasing the SiO_2 content. Thermal quenching of this kind of silicate phosphor is unsatisfactory for the emission intensity decreases by 62% when the temperature rises to 150°C compared to the initial intensity measured at room temperature. Though the luminescence efficiency of $\text{Sr}_2\text{SiO}_4\text{:Eu}^{2+}$ is comparable with YAG:Ce^{3+} , the thermal stability and structure stability are still limitations for its applications.

Nitride Red Phosphors [3]

1. $\text{M}_2\text{Si}_5\text{N}_8\text{:Eu}^{2+}$ (M = Ca, Sr, Ba) phosphors

Crystal structure: $\text{Ca}_2\text{Si}_5\text{N}_8$ has a monoclinic crystal system with the space group of Cc, whereas both $\text{Sr}_2\text{Si}_5\text{N}_8$ and $\text{Ba}_2\text{Si}_5\text{N}_8$ belong to orthorhombic crystal system with the space group of Pmn2₁. There are two different crystallographic sites for alkaline earth metals. Each Ca^{2+} ion in $\text{Ca}_2\text{Si}_5\text{N}_8$ is coordinated by seven nitrogen ions, while Sr^{2+} and Ba^{2+} in $\text{Sr}_2\text{Si}_5\text{N}_8$ and $\text{Ba}_2\text{Si}_5\text{N}_8$ are coordinated by eight or nine nitrogen ions.

Luminescent properties: The $\text{M}_2\text{Si}_5\text{N}_8\text{:Eu}^{2+}$ (M = Ca, Sr, Ba) phosphors show very intense red emission under blue light excitation. The emission color changes from orange to deep red depending on the alkaline earth metal ion ratio. The emission spectra all exhibit a broad and asymmetrical band extending from 550 to 850 nm. Upon the 450 nm excitation, $\text{Sr}_2\text{Si}_5\text{N}_8\text{:Eu}^{2+}$ shows an absorption and external quantum efficiency of 87% and 71%, respectively.

2. $\text{CaAlSiN}_3\text{:Eu}^{2+}$ phosphor

Crystal structure: CaAlSiN_3 belongs to orthorhombic crystal system with Cmc2₁ space group. The Ca^{2+} ions have only one crystallographic site, which is coordinated by five nitrogen ions.

Luminescent properties: The excitation spectrum covers a broad spectral range of 250–600 nm, showing an extremely broad band and strong absorption of visible light.

The emission spectrum extends from 550 to 800 nm, showing a broad band centered at 655 nm with a FWHM value of 93 nm. When the phosphor is excited by the blue light ($\lambda = 450$ nm), the external quantum efficiency is up to 70%. In addition, it has a slight thermal quenching. The luminescence is quenched by 10% of the initial intensity when the phosphor is heated to 150 °C and excited at 450 nm.

Definition

Photodetectors or photosensors are sensors that are used to transform incoming optical energy into electrical signals. A photodetector used in the application field of color science and technology typically covers the visible spectrum wavelength range from 380 to 780 nm.

Overview

Photodetectors are transducers that transform one of their characteristics when light energy impinges on them. In this category, photoresistors alter their ohmic resistance, rods, and cones of the retina neurons of the eye alter their electrochemical response, and chlorophyll in plant leaves changes the rate of converting CO_2 to O_2 . Some other photodetectors alter the flow of electrical current or the potential difference across their terminals.

Photodetectors with sufficiently fast response that provide a measurable output for a small amount of light are easily reproducible and are economical and worth investigating for applications in high-speed optical communications. This category includes avalanche photodiodes (APDs) and positive intrinsic negative photodiodes (PINs).

Specifications of photodetectors are characterized by key parameters as follows, spectral response, photosensitivity, quantum efficiency, dark current, forward-biased noise, noise equivalent power, terminal capacitance, timing response, frequency bandwidth, and cutoff frequency.

Figure 1 shows a typical photodetector. It includes three stages: (1) to generate electron–hole pairs or electrons in photosensitive material using an incident light; (2) to transform them through a bias provided by a power supply; and (3) to output the electrical signal directly or via an amplifier [1–5].

Photodiode and Photomultiplier Tube

Figure 1 shows a photodiode, a circuit including a p–n junction semiconductor and can output electrical signal. It can be seen that the photosensitive

material includes a p–n junction, a boundary or interface between n-type and p-type semiconductors, and a depleted semiconductor region with a high electric field that can separate the electron–hole pair.

As incident light on a photocathode (photosensitive material is made of a multi-alkaline material, for example), it generates photoelectrons; next, the generated photoelectrons travel in a vacuum tube and hit the first dynode and generate secondary electrons. Then, the secondary electrons are multiplied by a series of

dynodes and reach an anode to produce an electrical signal. As the electrical signal is multiplied many times and the whole process is performed in a vacuum tube to prevent electron absorption by the air, it is called a photomultiplier tube (PMT), as shown in Fig. 2.

Photodiode Array and Charge-Coupled Device

As the discrete photodiodes form an array with an integrated circuit board, it is called a photodiode array. As an integrated circuit contains an array of capacitors that store charge of electron–hole pairs created by photosensitive material, it is called a charge-coupled device (CCD).

Applications

In color applications, photodetectors are included in many color measuring instruments, which measure parameters such as luminance, illuminance, or chromaticity. Sze and Ng divided photodetectors into four categories: photoconductor, photodiode, avalanche photodiode, and phototransistor [1]. The photodiode and the phototransistor are typically used in color applications.

Photodetector, Fig. 1 A schematic diagram of a photodetector (i.e., also a photodiode)

Photodetector, Fig. 2 A schematic diagram to show a photomultiplier tube. The incident light through the window hits a photocathode (photosensitive material is made by a multi-alkaline material, for example). It generates photoelectrons, which transmit in a vacuum, hit on the first dynode, and is then multiplied by a series of dynodes,

finally reaching an anode to produce an amplified electrical signal. To prevent the absorption of photoelectrons and generated electrons into the air, a vacuum tube is used. Finally, the output electrical signal is amplified 10^4 – 10^5 times and within in a pico-ampere to micro-ampere current range

Photodetector, Fig. 3 The schematic diagram of an image luminance measuring device (ILMD). The captured color image via an ILMD, and then transformed into

a luminance image through the analyzer, and the luminance distribution can be used for many applications, such as to calculate the glare index for lighting applications

An Si photodiode together with a filter to mimic the luminous efficiency function (i.e., $V(\lambda)$ filter) becomes a $V(\lambda)$ photodetector, which is used for measuring the luminance (in cd/m^2 units). In a colorimeter, an Si photodiode combined with filters to mimic the color-matching functions of $\bar{x}$, $\bar{y}$, and $\bar{z}$ are used to measure CIE tristimulus values (X, Y, and Z).

A PMT can detect dim light; it usually works with a monochromator. This arrangement can measure spectral information across the spectrum. The measured spectra multiplying the luminous efficiency function $V(\lambda)$ can obtain luminance.

In color applications, a photodiode array is placed in an array image plane to form an image-based colorimeter. A CCD combined with the desired color filters measures an array of chromaticity values. Recently, in the display and imaging industry, CCD has been replaced by a complementary metal-oxide semiconductor (CMOS) as

an image-type photodetector because of its low cost. Figure 3 shows an image luminance measurement device (ILMD) that applies a commercial color CCD camera or color CMOS camera to measure the quality of roadway lighting [6]. ILMD is widely used for measuring luminaires of tunnel lighting, outdoor day-lite, indoor lighting (uniformity, contrast, glare, etc.), and near-field goniophotometry as well.

Definition

The expression and molecular structure of the genes encoding the human cone photopigments is the first step in determining our color vision. Alterations in these genes have consequences for the spectral sensitivity of the cone photoreceptors, which in turn affect how color-normal and color-deficient individuals see the world.

Overview

Normal trichromats can match any given color by combining three suitably chosen primaries (such as red, green, and blue) in appropriate proportions. Color-deficient individuals differ from normal trichromats with respect to the proportions of the primaries required for a match: they may use the three primaries in unusual quantities or they may only use two primaries. The first type of variation is known as anomalous trichromacy, which is assumed to arise when three classes of cones are present, one of which contains a photopigment with an anomalous absorption spectrum. The second type of variation is known as dichromacy, which occurs if only two of the three classes of cone – short (S), middle (M), or long (L) wavelength-sensitive – may be affected, manifesting in different color vision phenotypes. The different phenotypes are associated with predictable patterns of color-matching behavior, which can be identified easily using psychophysical tests of color vision. The presence and sequence of the genes encoding the photopigment genes ultimately determine the individual's genotype and can be identified by examining their deoxyribonucleic acid (DNA). Research into the empirical relation between underlying genotype and expressed phenotype has led to improved understanding of the physiological mechanisms responsible for variations in human color vision.

Nathans and colleagues [1] were the first to utilize advances in molecular genetics to study human photopigment genes, using a technique that involves in vitro construction of DNA molecules to produce recombinant DNA. Photopigments are the light-absorbing

molecules that mediate vision, with absorption maxima (λ_{max}) at approximately 420 nm (S-cone), 530 nm (M-cone), and 560 nm (L-cone). Structurally, they consist of opsin – transmembrane heptahelical proteins of a single polypeptide chain, composed of either 364 (*OPN1LW* and *OPN1MW* for the L- and M-cones, respectively) or 348 (*OPN1SW* for the S-cone) amino acids – bound to a chromophore: 11-*cis* retinal. Photon absorption by the pigment molecules causes isomerization of the chromophore from “11-*cis*” to “all-*trans*” form, which initiates a signal cascade, known as photo-transduction. The binding socket site of the chromophore in both the cone and rod opsins is located in helix 7 (Fig. 1).

The precise λ_{max} of a given pigment will be determined by the amino acid sequence of the opsin and the interaction of specific amino acids with retinal [3]. Whereas the λ_{max} of 11-*cis*

retinal is 375 nm [4, 5], the exact amino acid sequence of opsin “spectrally tunes” the pigment to a specific wavelength [6, 7] by shifting it toward the “red” end of the spectrum. Research with retinal organoids suggests that the fate of a given cone cell is determined by thyroid hormone signaling, with specification of S-cones occurring early in development and the remaining cones being specified as L vs M later [8]. The number and distribution of the three cone classes are not equal, either between individuals or across a given retina. In the normal eye, S-cones comprise approximately 7–10% of the total cone population and are even sparser at the fovea [9, 10] which may account for some of the variation in chromatic sensitivity observed across the retina [11]. The remaining cones are specified as L or M, the proportion of which, unlike S-cones, is highly variable and has been shown to range from around 50–95% L-cones in the normal eye [12].

Photoreceptors, Color Vision, Fig. 1 Arrangement of visual pigments in a cone photoreceptor. The infolding membrane of the cone outer segment is packed with photopigment molecules. The molecule consists of seven α -helices which span the membrane of the cell surrounding the chromophore: 11-*cis* retinal. The NH₂ (N) terminus is extracellular, whereas the COOH (C) terminus is intracellular. Shown in the bottom right is the sequence of amino

acids that make up this heptahelical molecule. White circles represent amino acids that are identical across the L- and M-cone pigments, and black circles represent amino acids that are different. The substitutions at positions 180, 277, and 285 are believed to contribute most of the spectral difference between the M- and L-cone pigments. (Adapted from Sharpe [2] and Nathans [1])

The genes encoding the S-cone pigments reside alone as a single copy on the q-arm (long arm) of chromosome 7 [13]. The genes encoding the L- and M-cone pigments reside on the q-arm of the X-chromosome, organized in a tandem array [1] of up to six exons (coding regions of DNA) separated by relatively long introns (non-coding regions of DNA) (Fig. 3). The S-cone pigment shows only $43 \pm 1\%$ analogy in the amino acid sequence when compared to either the M- or L-cone photopigments. In contrast, the M- and L-cone pigment genes are 96% homologous, differing only in 15 amino acids [2]. The approximate 30 nm spectral difference between these two visual pigments is attributable to substitutions at these particular amino acid positions confined to exons 2–5. The largest shifts in λ_{max} are produced by substitutions at two key sites within exon 5: amino acid positions 277 (~ 7 nm) and 285 (~ 14 nm) (Fig. 1). These result in spectral shifts of 15–25 nm; the exact value depends on sequences in exons 2–4. Substitutions within exons 2–4 produce much smaller shifts of less than ~ 4 nm and may be responsible for the subtle individual differences in color vision among normal and anomalous trichromats. Both in vitro methods to investigate protein sequence variation [1, 6] and in vivo methods to probe spectral sensitivity [14] have shown that amino acid substitutions in exon 2 contribute very little to spectral tuning (0.0–0.7 nm) [6, 14]. More recently, it has been speculated that the amino acid differences in exon 2 are involved in controlling the optical density of the L- and M-cone photopigments [15]. The optical density depends on the concentration of the photopigment in the cone outer segment, the length of the cone outer segment, and also the extinction coefficient, which describes the probability of a photon being absorbed [16]. An increase in effective optical density of cones causes a broadening of the spectral sensitivity curve (Fig. 2), such that if two genes that differ only in their exon 2 sequences are expressed, the resulting differences in the optical density of the photopigments may account for some residual color discrimination [15].

The high homology of the L- and M-cone pigment genes suggests evolution from a single

Photoreceptors, Color Vision, Fig. 2 Theoretical spectral sensitivity curves for the L-cone pigment. Changes in the optical density of the cone pigment may occur from amino acid substitutions in exon 2, altering the stability of the molecule or the efficiency with which it absorbs light. For wavelengths near the peak, the optical density qualitatively mimics the difference that would be produced by a spectral shift

gene. Comparison of amino acid sequences indicates that S-cones and rod receptors arose first from a common ancestral receptor. From comparisons with contemporary New World monkeys, which have only two cone photopigments, it is thought that a long wavelength gene duplicated and diverged to originate the L- and M-cone photopigments, at the time when Old World monkeys (trichromatic) separated from New World monkeys [1, 17]. The location of the *OPN1LW* and *OPN1MW* genes on the X-chromosome can account for the larger number of (red/green) color-deficient men compared to women, as men have only one X-chromosome. The head to tail arrangement of the *OPN1LW/OPN1MW* genes makes them susceptible to mispairing during meiosis, leading to unequal crossing over between gene arrays. If the crossover occurs between genes, this will result in the deletion of a gene from one chromosome and its addition to the other, whereas a crossover within a gene will lead to the production of a hybrid gene that

Photoreceptors, Color Vision, Fig. 3 Schematic of the tandem array of L- and M-cones on the q-arm of the X chromosome. (a) The LCR (locus control region) can activate only one of the promoter regions just upstream of a gene. The promoters are regulatory units upstream (or to the left) of the transcription site and regulate the rate of DNA transcription into RNA and hence the amount of

opsin gene expression. The opsin-coding sequences are divided into exons (black bars). The intron sequences (gaps) are silent or noncoding and have no apparent function. (b) Schematic of unequal intragenic crossover that would produce hybrid genes. (Adapted from Neitz and Neitz [18])

combines regions of the L and M genes into a single gene. Such hybrid genes are thought to be the genetic basis responsible for the majority of color vision defects [1].

Figure 3 shows an example of how the formation of hybrid genes produces pigments with abnormal spectral sensitivity. The spectral sensitivity of the photopigment will depend on which of the *OPN1LW*/*OPN1MW* genes the crossover originated from [19]. Visual pigment gene arrays for people with normal color vision have an *OPN1LW* gene in the most upstream (or leftmost) position, with one or more *OPN1MW* genes downstream (or to the right) of the *OPN1LW* gene. Normal trichromats usually have only one copy of *OPN1LW*, multiple copies of *OPN1MW*, and possibly a number of hybrids [2]. There is good evidence from studies of gene expression in the retina and from studies involving genotype-phenotype relationships [20] that

only the first two genes are expressed and play a significant role in color vision. Whereas normal trichromats have *OPN1LW* and *OPN1MW* occupying the two most proximal positions of the array from the locus control region (LCR), anomalous trichromats instead have a hybrid gene positioned in either the first or second position. Deutan deficiencies arise when there is no M-sensitive photopigment, whereas protan deficiencies arise from a lack of L-sensitive photopigment. If there is only one opsin gene, or two with identical spectral sensitivity, the resulting phenotype will be dichromacy (deuteranopia or protanopia). If, however, the first two genes in the array encode opsins with different spectral sensitivity, as can be introduced by a hybrid, the result will be anomalous trichromacy (deuteranomaly or protanomaly) [7]. The propensity for the *OPN1LW* and *OPN1MW* genes to cross over creates the opportunity for multiple combinations, producing

numerous polymorphisms and hybrid variants, which are thought to underlie the high variability in red/green color vision observed even within the normal population [18].

In addition to the creation of hybrid genes, mutations within the *OPN1LW/OPN1MW* array can produce cones that are nonfunctional and even degenerative, depending on the amount of correctly spliced precursor messenger ribonucleic acid (RNA) [21]. High-resolution retinal imaging has shown that those with genes encoding functional (even if altered) opsin in one or both proximal positions of the array present with a contiguous mosaic of cone photoreceptors [22]. As such, other non-chromatic aspects of visual function in single or multigene dichromats are usually unaffected [23]. In contrast, retinal imaging in those with genes encoding nonfunctional opsin reveals variable disruption of the cone mosaic [24], which may be associated with other visual deficits, such as myopia [25].

The *OPN1SW* opsin gene sequence is nearly invariant in the human population; however further genotype-phenotype studies are yet to be performed to prove this. Intragenic crossover – the mechanism that permits the frequent manifestation of anomaly in protan and deutan defects – has no analogy in tritan defects. Six mutations have been established causing amino acid substitutions that perturb the structure or stability of the S-cone photopigment [13, 26], therefore strongly affecting the performance of the S-cone photoreceptors. On the other hand, no polymorphisms causing shifts in $\lambda_{\max}$ have been reported so far, and only one substitution was found in the coding sequences and exon-intron junctions, which has no impact on its spectral characteristics [27]. However, abnormalities as a result of genetic variation in *OPN1SW* may have less likelihood of being detected, as any small variations in $\lambda_{\max}$ would be difficult to dissociate from individual variations in macular pigment and lens density measured psychophysically or in vivo. Testing patients with blue cone monochromacy, for whom cone function is isolated to the S-cones [28], may enable detection of individual differences in S-cone spectral sensitivity, although its

low prevalence (~1/100,000) limits the opportunities for such research studies.

Future Directions

An important consideration in the study of human color vision is how spectral differences between photopigments translate to performance on color-related tasks. There are numerous retinal and cortical factors that influence chromatic discrimination; it is therefore insufficient to simply compare differences in $\lambda_{\max}$. For example, there have been shown to be large differences in L:M cone ratio [12] even among family members with the same genotype [25]; how such differences could interact with hybrid genes and mutations to affect color vision is not well understood. When color vision depends on subtle differences between L- and M-cone pigments, as in anomalous trichromacy, polymorphisms that might affect optical density as well as those that shift $\lambda_{\max}$ must be accounted for. It has been suggested that a L/M separation greater than ~20 nm would be sufficient to account for normal color vision, implying that normal trichromats can, in principle, have visual pigments encoded by hybrid genes, providing that the $\lambda_{\max}$ values of the two hybrids remains greater than 20 nm apart.

Changes in $\lambda_{\max}$, photoreceptor optical densities, and/or post-receptoral amplification of cone signals appear to be the most important parameters that affect our red-green chromatic sensitivity. In addition to cone photoreceptors, rods and melanopsin also form part of the process [29], particularly under certain low lighting conditions [30] or in color deficiency or cone dysfunction [31, 32]. Establishing the relative importance of each of these parameters in determining an individual's color discrimination performance therefore remains a difficult task. A marriage of information derived from genetic analysis of pigment genes, in vitro and in vivo characterization of cone cells, psychophysical data on chromatic sensitivity, and theoretical modeling is therefore needed in order to produce a comprehensive

description of mechanisms that underlie human color vision in all its complexity.

Definition

A ceramic pigment is usually a metal transition complex oxide obtained by a calcination process which shows three main characteristics: (a) thermal stability, maintaining its identity when temperature increases; (b) chemical stability, maintaining its identity when fired with glazes or ceramic matrices; and (c) high tinting strength when dispersed and fired with glazes or ceramic matrices. Other characteristics as high dispersability in vehicles, high refractive index (in order to avoid transparency and to increase its tinting strength), acid and alkali resistance, and low abrasive strength are also suitable.

The main coloring methods of ceramics are based on dyes or pigments. Strictly a dye or soluble colorant is a colored substance that interacts with the matrix to which it is applied and usually is soluble in the media of application called matrix or substrate. Conversely, ideally a pigment or stain is a colored substance insoluble in the pigmented matrix, is stable in the matrix (it does not interact with the matrix), and, in the case of ceramic pigments used in stoneware or glazes, is stable when temperature increases (thermal stability). Obviously a pigment must have a high tinting strength relative to the materials it colors. As a general rule, ceramic stains and ceramic pigments look pretty much the same before and after firing, but not dyes, based on raw oxides as well as salts such as carbonates or nitrates, because they decompose in firing and dissolve in the glazes or stoneware (Fig. 1a) [1a].

Pigment, Ceramic, Fig. 1 (a) Ideal behavior of interaction of pigments (dispersion) and dyes (dissolution) with the matrix. (b) Color evolution with the firing temperature of screen printing (90 threads/cm) deposition of a Co-Ti

ink (1 w.% in the organic polyol media) under a glazed CaO-ZnO-SiO₂ monoporosa tile (previously fired at 1,080 °C)

Industrial Ceramic Pigments

In the industry there are several steps for the production of industrial ceramic pigments:

- 1. Grinding. The raw materials (usually oxides or carbonates) are carefully mixed in mills such as ball mills often with mineralizer agents (inorganic salts as NaCl, NaF, and KNO₃) in order to facilitate the pigment crystallization.

2. Calcination. The mixture is then calcined in either batch kilns or continuous calciners.
3. Washing. After calcination, the powders are washed to eliminate residual salts from mineralizers and other leaching components in order to avoid future firing defects and environmental affections.
4. Micronization. The mixture is then ground to the necessary fineness in mills. Micronizers and jet mills are used to break agglomerates.
5. Tinting strength control. The final production step involves careful control of the color tone.

Because these pigments are formed at high temperatures, they generally offer superb thermal stability and are relatively inert. This results in excellent weathering and light fastness properties. Most of these pigments have superior acid and alkali resistance. They are nonmigrating and nonbleeding in nature and do not interact with substrates. The principal disadvantage of ceramic pigments is their low tinting strength. In addition, some are relatively high in cost. This is particularly true with cobalt-containing pigments. Some of these pigments are difficult to disperse. However, the recent development of easily dispersed ceramic pigments should eliminate this problem. A final concern is the inherent hardness of these pigments. Their hardness can lead to processing system damage through abrasion. When using ceramic pigments, processing system components designed for use with abrasive materials should be considered [1b].

Overview

Stable fired pigments solve some of the problems found in using dyes such as: (a) the use of hazardous raw materials, because many of the unstable oxides or salts used as direct dyes are soluble or toxic, its calcination, by combining these elements along with clays, silica, alumina, etc., makes them stable giving a safety manipulation, is the case of vanadium pentoxide a toxic substance that is safely used in the zirconium vanadium blue zircon ceramic pigment, (b) volatilization in the kiln which is colored by

the fumes such as it occurs using vanadium oxide or chromium oxide, and (c) the own stability of the color avoiding chemical reactions of the dye with the components of the glaze, for example, eskolaite Cr_2O_3 , used as natural green dye, reacts with tin oxide and silica of the glazes producing malayaite Cr-CaSnSiO_5 pink precipitates, and then a pink undesired coloration is given, or reacts with zinc oxide of the glaze to crystallize ZnCr_2O_4 spinel, imparting undesired blue-brown color; the use of the cobalt-zinc-alumina-chromite blue-green pigment gives a trustworthy stable range of color from green to blue.

How to give trustworthy and safety color to ceramics is the main proposal of pigment production because adding color to our ceramics is needed to produce ceramic art and it cannot be a tricky proposition. Working with paints, the color you put on your piece is the color of the final paint, but in ceramics the fire also builds the color. Pigment research is addressed to obtain new ceramic pigments in order to reach three main purposes:

- (a) High thermal stability pigments, addressed to new materials as porcelainized stoneware and correlated use of ink-jet printing techniques, that require obtaining adequate particle size of pigments or precursor solutions that produce the pigment “in situ,” during thermal processing of substrate.
- (b) High chemical resistance pigments, adapted to new glazes and ceramic matrices avoiding particle pigment solubilization or degradation when it reacts in ceramic processing.
- (c) Eco-friendly pigments, with low environmental affection evaluated on its complete life cycle: raw material preparation, transport, processing, product distribution, and waste management.
- (d) Pigments for industrial digital printing (ink-jet). Ink-jet decoration is a relatively recent methodology. Elmquist designed the first practice application of CIJ (continuous ink-jet) in 1951 for tape recorder. Winston developed the first teletype printer by CIJ, and in 1968 the first commercial printer 9600 from AB Dick appeared. A continuous

flow of electrical conductive ink drops is thrown to substrate and selectively dispersed by an electric field in the CIJ ancient technology. The DOD (drop on demand) ink-jet was developed later in order to produce only the demanded drops. Firstly, in TIJ (thermal ink-jet) technique, the drops were produced from pressure of bubbles generated into the nozzles by a local heating mechanism. Now, in the PIJ (piezoelectric ink-jet) technique, the drops are produced by pressure due to the deformation when an electric field is applied to a piezoelectric piece disposed in the nozzles.

Digital decoration technology is widely developed in other materials (textile, paper, etc.), basically using TIJ technique. It has been claimed for surface ceramic tile decoration due to several advantages based on the fact of absence of contact between the applicator and the decorated surface:

- (i) High resolution of images. The ink-jet technique allows to throw 2,000–5,000 drops/cm in a strictly controlled way. Using serigraphy, chalcography, or flexography methods, the resolution is very limited. Therefore photographic quality images could be carefully reproduced by ink-jet digital monitored application.
- (ii) Low raw strength of tile and short enameling line required. Due to the absence of contact applicator surface, the raw strength is limited only to the adequate manipulation of raw tile, and then the thickness of piece can be reduced. The number of decoration operations is reduced sometimes at one because it can be applied four colors in a selective way at the same time; likewise the reduced weight of ink deposited and relatively low water concentration reduce the drying time between successive applications, and therefore the length of industrial enameling line is drastically reduced.
- (iii) The topography of the tile surface is not limited and relief surfaces can be easily decorated.

- (iv) Reduction of necessary ink (1 g/m^2), fully recycling and washing operations eliminated.
- (v) Simplicity of the decoration process because it can be limited to only one decoration step using the simultaneous four-color application CMYK (cyan, magenta, yellow, black).

The main difficulty for ink-jet application in ceramic tile industry is the ink that must show specific properties, basically:

- (i) High stability, because the precipitation, agglomeration, or viscosity changes can obstruct the nozzles.
- (ii) High color strength is necessary due to reduced weight of ink deposited by dropping; on contrary, diffused and weak colors are obtained and poor decoration is produced.
- (iii) Neutral pH is required in order to prevent corrosive effects on the nozzles, but conductivity is not required in both PIJ or TIJ technologies; contrarily in ancient CIJ technique, the electric charge capacity of drops was necessary for their selective dispersion by an electric field.

There are three main families of digital inks: (a) soluble salts such as cobalt nitrate (*CYAN*), mixture of chromium nitrate and iron nitrate (*MAGENTA*), mixture of antimony nitrate, nicke and stabilized titania (*YELLOW*), and mixtures of cobalt and iron nitrates (*BLACK*) are used for producing “in situ,” when decorated ceramics are fired, classical ceramic pigments such as Co_2SiO_4 olivine blue pigment, $\text{Fe}(\text{Fe},\text{Cr})_2\text{O}_4$ iron chromite brown spinel, $(\text{Ti},\text{Ni},\text{Sb})\text{O}_2$ chromium-antimony yellow rutile, and CoFe_2O_4 black spinel, respectively; (b) colloidal or ultra-micronized classical pigments particles dispersed using dispersant agents; and (c) nanoparticles of classical ceramic pigments, produced by “soft chemistry” such as polyol or sol-gel routes, or metals absorbed on stable sol particles of oxohydroxy compounds of Al, Ti, Sn or Zr (purple of Cassius and its analogous with Cu).

Since the nineteenth century, needs on color stability, glaze resistance, and sure management lead to stabilized fired pigments. On these pigmenting systems, chromophore agents (usually first row transition heavy metals and p metals) are inertized in high-thermal and low-solubility ceramic matrices.

The main mechanisms of origin of color based on the stabilization-inertization of chromophores are the following:

- (a) Structural mechanism. In this case the chromophore cations (usually transition metals that absorb, as it is discussed below, selected visible wavelengths by d-d electron transitions) are forming the ceramic network such as Co(II) in Co_2SiO_4 olivine. In other structural cases, a solid solution is obtained: pigmenting cations substitute structural cations in ceramic matrix as V^{4+} substitutes Zr^{4+} in ZrSiO_4 zirconium vanadium blue zircon (a cyan pigment also named Turkish blue zircon or turquoise zircon) formulated by CPMA as $(\text{V,Zr})\text{SiO}_4$. The above-discussed classical pigments $\text{Fe}(\text{Fe,Cr})_2\text{O}_4$ (iron chromite brown spinel with iron in solid solution into chromite network) and $(\text{Ti,Ni,Sb})\text{O}_2$ (chromium-antimony yellow rutile with Sb^{+5} and Cr^{3+} in solid solution into rutile lattice), are also solid solutions.
- (b) Inclusion mechanisms. Colored nanoparticles protected into high stable host crystals (e.g. Fe_2O_3 hematite into zircon crystal particles that gives the pink coral of iron in the zircon ceramic pigment) are the origin of color in this case.
- (c) Mordant mechanism. The origin of color is in this case a metal-based dye stabilized by a mordant compound. The final color depends on the mordant used, due to the formation of metal complexes that cause a change in the molecular orbital energies and hence a shift in UV-Vis absorption bands; e.g. Au in $\text{Sn}(\text{OH})_4$ mordant substrate on Cassius purple pigment [1a].

In agreement with above-described purposes of research on new ceramic pigments, three main

limitations can be pointed out: (a) thermal and chemical stability, (b) structure base, and (c) environmental safety. These limitations are described and illustrated with three examples.

Thermal and Chemical Stability: Cobalt Inks

Usually cobalt oxide Co_3O_4 used as cobalt precursor raw material is a mixed valence oxide of Co^{2+} and Co^{3+} with spinel structure $\text{Co}^{\text{II}}\text{Co}_2^{\text{III}}\text{O}_4$ which decompose on firing by reducing the unstable Co^{3+} to Co^{2+} producing a profuse pinhole in the glazes if the time of firing is not sufficient due to oxygen release:

The Co^{2+} ion dissolves in ceramic glazes and imparts an intense blue color to ceramic glazes up to 0.05 w.% and could be used in novel dye ink-jet application in ceramics. This color intensifies in the presence of ZnO, due to the crystallization of a solid solution of Co^{2+} in willemite $(\text{Zn}, \text{Co})_2(\text{SiO}_4)_2$, or in the presence of BaO which precipitates cobalt-celsian solid solution $(\text{Ba}, \text{Co})(\text{SiO}_4)_2$. In glazes containing MgO and TiO_2 , cobalt gives green colorations, due to crystallization of green cobalt-ilmenite CoTiO_3 more stable in boron glazes [1c].

The color evolution with the firing temperature of screen printing (90 threads/cm) deposition of a Co-Ti ink (1 w.% in the organic polyol media) over a glazed “monoporosa” tile (previously fired a 1,080 °C) is shown in Fig. 1b. The green coloration at low temperatures (820, 925 °C) is associated to cobalt-ilmenite CoTiO_3 crystallizations with Co^{2+} in octahedral coordination (absorption bands at 350 nm in the UV range, 700 nm in the visible red wavelength, and 1,200 nm in the IR range, in the spectral and color rendering of Fig. 1). When temperature increases, the cobalt-ilmenite CoTiO_3 decomposes and Co^{2+} solubilizes in the glaze giving intense blue color associated to Co^{2+} in tetrahedral coordination (absorption bands at 530 nm green, 590 nm orange, and 650 nm red and high reflectivity at

430 nm blue wavelength). At low temperature the color is associated to a pigment mechanism (particles of ilmenite crystallization on the glaze surface), but at high temperatures, the color is due to a dye mechanism (cobalt dissolution in glaze).

Structure Base: The Classical Pigment Palette

A useful colorant classification of the chemicals used as ceramic pigments was reached in 1977 from the requirements of the Toxic Substances Control Act, 94–469 US law, which includes the whole chemical substances used in the USA whether they are toxic or not. The Dry Colors Manufacturer's Association (DCMA) commends to their Metal Oxide and Ceramic Color Subcommittee of DCMA Ecology Committee the classification of the commercial ceramic pigments giving a standard terminology. This DCMA committee applied a chemical-structural criteria for the classification of ceramic pigments in 14 structural families: (1) baddeleyite [1 ceramic pigment], (2) borate [1], (3) corundum-hematite [4], (4) garnet [1], (5) olivine [2], (6) periclase [1], (7) phenacite-willemitite [1], (8) phosphate [2], (9) priderite [1], (10) pyrochlore [1], (11) rutile-cassiterite [11], (12) sphene [1], (13) spinel [19], and (14) zircon [3 ceramic pigments].

In 2010 the Color Pigments Manufacturers Association (CPMA) actualized the classification and chemical description of the complex inorganic color pigments in the fourth edition [2]. CPMA describes the industrial ceramic pigment by a code such as CPMA 1-01-4. The first number on the code is the corresponding number of the structure above discussed (in this case 1 = baddeleyite), the second set is the CPMA category number identifying each pigment within a given crystal class (in this case 1 = first ceramic pigment on the CPMA list), and the third set of numbers identifies the color of the pigment as follows: (1) violet and red-blue; (2) blue and blue-green; (3) green; (4) yellow and primrose; (5) pink, orchid, coral, and peach; (6) buff; (7) brown; (8) gray; and (9) black (in the above case 4 = yellow). Finally, CPMA also gives a

classification based upon the predominant use of these pigments; three use categories were adopted for guidance. Category A deals with pigments suspended in glass matrices which require the highest degree of heat stability and chemical resistance to withstand the attack of molten glass. Category B deals with pigments suspended in plastics and other polymers which require only moderate heat stability. Category C deals with pigments suspended in liquid vehicles which require little or no heat stability.

Among the more successful ceramic pigments which gives a complete CMYK palette of color, the pigments based on zircon structure (number XIV in CPMA classification) shown in Fig. 2a and discovered by C. A. Seabright in 1948 stand out.

- (a) CYAN based on the vanadium blue zircon $V\text{-ZrSiO}_4$ (CPMA number 14-42-2). CPMA describes this pigment as an inorganic pigment and as a reaction product of high-temperature calcination in which zirconium (IV) oxide, silicon (IV) oxide, and vanadium (IV) oxide in varying amounts are homogeneously and ionically interdiffused to form a crystalline matrix of zircon. Basic chemical formula: $(Zr,V)SiO_4$. Its composition may include any one or a combination of the modifiers alkali or alkaline earth halides. Use category A. Exceptionally suitable for coloring ceramic glazes and clay bodies. Not generally used in porcelain enamels.
- (b) MAGENTA based on the pink coral $Fe\text{-ZrSiO}_4$ (CPMA number 14-44-5). CPMA describes the zirconium iron pink (peach, coral) zircon, as an inorganic pigment, as a reaction product of high-temperature calcination in which zirconium (IV) oxide, silicon (IV) oxide, and iron (III) oxide in varying amounts are homogeneously and ionically interdiffused to form a crystalline matrix of zircon. Basic chemical formula: $(Zr,Fe)SiO_4$. Its composition may include any one or a combination of the modifiers alkali or alkaline earth halides. Use category A. Exceptionally suitable for coloring ceramic glazes. Not generally used in clay bodies or porcelain enamels.

Pigment, Ceramic, Fig. 2 (a) ZrSiO_4 structure from CPMA classification, S.G. $I4_1/$ with D_{2d} symmetry for SiO_4 group and dodecahedral D_{2d} for ZrO_8 , (b) CMYK subtractive color model, (c) RGB additive color model, (d) the CMYK zircon palette (*cyan* (Zr,V) SiO_4 DCMA

14-42-2, *pink* (Zr,Fe) SiO_4 DCMA 14-44-5, *yellow* (Zr,Pr) SiO_4 DCMA 14-43-4) including a Cr,Co-ferrite as *black* component, all 3% enameled in monoporosa glaze, (e) particles of black spinel pigment by SEM

P

(c) **YELLOW** based on the yellow of praseodymium Pr-ZrSiO_4 (CPMA number 14-43-4). CPMA describes the zirconium praseodymium yellow zircon, as an inorganic pigment, as a reaction product of high-temperature calcination in which zirconium (IV) oxide, silicon (IV) oxide, and praseodymium (III, IV) oxide (Pr_6O_{11}) in varying amounts are homogeneously and ionically interdiffused to form a crystalline matrix of zircon. Basic chemical formula: $(\text{Zr,Pr})\text{SiO}_4$. Its composition may include any one or a combination of the modifiers alkali or alkaline earth halides. Use category A. Exceptionally suitable for coloring

ceramic glazes and clay bodies. Not generally used in porcelain enamels.

(d) **BLACK** usually obtained from spinel structure in CPMA classification such as the ferrite $(\text{Mg}_{0.5}\text{Fe}_{0.5})(\text{Co}_{0.5}\text{Fe}_{1.4}\text{Cr}_{0.1})\text{O}_4$ shown in Fig. 2d. CPMA describes the iron cobalt chromite black spinel as an inorganic pigment and as a reaction product of high-temperature calcination in which iron (II) oxide, cobalt (II) oxide, iron (III) oxide, and chromium (III) oxide in varying amounts are homogeneously and ionically interdiffused to form a crystalline matrix of spinel. Basic chemical formula: $(\text{Co,Fe})(\text{Fe,Cr})_2\text{O}_4$. Its composition

may include any one or a combination of the modifiers Al_2O_3 , B_2O_3 , CuO , MnO , NiO , or SiO_2 . Use categories A, B, and C. Predominantly used for coloring category A substrates.

Adequate mixtures of above-described pigments may produce all range of visible colors, using the subtractive color vision model CMYK (where C = cyan, M = magenta, Y = yellow, and K = key associated to a mixture of C+M+Y which gives the black color) shown in Fig. 2b. in opposition to the additive color vision model RGB (R = red, G = green, B = blue) shown in Fig. 2c. Really the black color is not necessary because it could be built mixing CMY, but in ink and paints, it is used in order to simplify and to cheapen the printing manufacture. A detailed study of the CMY zircon pigments can be found in several doctoral theses [4, 5]. Really the color given by CMY zircon pigments is influenced by temperature and glaze or ceramic matrix; therefore usually a wider color palette must be used on pigmenting ceramics.

A total of 44 chemical substances are listed in the CPMA classification referred exclusively to industrial ceramic pigments. But the world of pigments is wider and, for example, on the industrial classification, the main red colors do not appear: the unstable purple of Cassius discovered by Johann Rudolph Glauber in 1659 and the sulfoselenide dated on 1909 and classified as harmful substance due to cadmium presence. The reddish ceramic pigments have been during centuries the driving force in the ceramic pigment field research [6]. The investigation on new host structures for pigmenting also has received attention, but usually, searching the red shades.

As example, a new color alternative to classical zircon palette can be obtained from the perovskite, a new and versatile lattice for ceramic pigments not considered on CPMA classification of industrial pigments. Neodymium perovskite pigments have been obtained by nonconventional methods [7–9]. Red, blue, green, and gray ceramic pigments based on FeNdO_3 perovskite (unmineralized sample or using $\text{BaF}_2+\text{MgF}_2$ flux agent for red and blue pigments, respectively) and CrNdO_3 (unmineralized sample or using

$\text{BaF}_2+\text{MgF}_2$ flux agent for green and gray pigments, respectively) can be obtained by ammonia coprecipitation from a solution of $\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$, $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, $\text{CrCl}_3 \cdot 6\text{H}_2\text{O}$ salts in water media.

Dried powders were successively fired at 1,000, 1,100, and 1,200 °C during 6 h of soaking time, and the obtained powders were 5% enameled in a conventional glaze (1,050 °C). Characterizations of samples are shown in Figs. 3 and 4:

- (a) Powder optical lens view ($\times 40$) (Fig. 3a) shows red, blue, green, and gray color of the respective perovskites.
- (b) XRD (X-Ray Diffraction) analysis carried out on a diffractometer, using Cu K_α radiation, 20–70 °2 θ range, scan rate 0.05 °2 θ /s, 10 s per step, and 40 kV and 20 mA conditions, shows that perovskite is the only crystalline phase detected in CrNdO_3 samples, but residual Nd_2O_3 peaks are always observed on FeNdO_3 samples (Fig. 3b).
- (c) 5 w.% enameled samples in a conventional glaze (1,050 °C) show the visual red, blue, green, and gray color of the respective perovskite color associated to CIEL*a*b* color measurements (Fig. 3c), which were measured following the CIE (Commission Internationale de l'Eclairage) colorimetric method using a spectrophotometer, with standard lighting D65 (natural daylight) and standard observer of 10°. On this method, L* is a measure of brightness (100 = white, 0 = black) and a* and b* of chroma (–a* = green, +a* = red, –b* = blue, +b* = yellow).
- (d) UV-Vis-NIR (Ultraviolet-Visible-Near Infrared) spectroscopy of enameled samples, collected using a spectrometer through diffuse reflectance technique, shows bands associated to Fe^{3+} in octahedral coordination (in FeNdO_3) or Cr^{3+} in octahedral coordination (in CrNdO_3), respectively, along with sharp bands associated to Nd^{3+} f-f transitions [12]. Samples with $\text{BaF}_2+\text{MgF}_2$ flux agent addition show similar bands to unmineralized samples, but the absorbance level increases in the Vis-NIR range producing dark colors (dark blue and black color, respectively, on Fig. 3c).

(b) UV-Vis-NIR spectra of $\text{Ca}_x\text{Y}_{2-x}\text{V}_x\text{Sn}_{2-x}\text{O}_{7.0,14}\text{Na}_2\text{SiF}_6$ powders, (c) SEM micrograph of $x = 0.16$ sample, (d) 5w% $x = 0.16$ glazed sample

The micrographs of samples of unmineralized and $\text{BaF}_2+\text{MgF}_2$ mineralized samples fired at $1,200^\circ\text{C}$, carried out by scanning electron microscopy (SEM), are shown in Fig. 4. Both samples show higher cubic crystalline morphology, but unmineralized sample shows higher size and heterogeneous particles that show low aggregation; in contrast $\text{BaF}_2+\text{MgF}_2$ mineralized sample shows a bimodal distribution of particle size (small $0.5\text{ }\mu\text{m}$ edge cubic particles and big $1.5\text{ }\mu\text{m}$ particles).

The preparation method of ceramic pigment allows obtaining new and best ceramic pigments.

There are different new methods of preparing ceramic pigments that produce new microstructures and solid solutions [1, 8].

Chemical methods as alternative to solid oxide reaction can be illustrated with above-discussed CrNdO_3 perovskite. A polyol route was used from $\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$ and $\text{CrCl}_3 \cdot 6\text{H}_2\text{O}$: salts were dissolved in 200 ml of DEG (diethylene glycol) to prepare 5 g. of final product, then refluxed at 150°C during 2 h, and then charred at $500^\circ\text{C}/1\text{ h}$ and fired at $1,100^\circ\text{C}$ with soaking time of 6 h. SEM micrograph of powders charred at 500°C shows aggregates of incipient cubes (Fig. 5c),

well developed in fired sample at 1,100 °C (Fig. 5d). Powder develops, 5 w.% enameled in conventional ceramic glaze (1,080 °C), good black shades ($L^*a^*b^* = 50.5/-0.6/1.0$) without mineralizer addition (compare Figs. 5b and 3c).

Therefore above neodymiums could be an example of alternative to cyan, pink, and black pigments to the classical zircon color palette. Finally an alternative to yellow of praseodymium in zircon could be a $\text{Ca}_x\text{Y}_{2-x}\text{V}_x\text{Sn}_{2-x}\text{O}_7$ yellow pigment based on pyrochlore crystal structure (Fd-3m) which describes materials of the types $\text{A}_2\text{B}_2\text{O}_6$ and $\text{A}_2\text{B}_2\text{O}_7$, where the A and B species are generally rare-earth or transition metal species, e.g., $\text{Y}_2\text{Ti}_2\text{O}_7$ [9]. A yellow pigment with the pyrochlore structure $\text{Ca}_x\text{Y}_{2-x}\text{V}_x\text{Ti}_{2-x}\text{O}_7$ is known since 1993 as a substitute for the decreasing variety of available yellow ceramic pigments due to the severe regulation of toxic lead and cadmium. The solubility limit of vanadium in this pigment was found to be 1.5 w.% as V_2O_5 or 0.13 as x in the above formula expression. Characterization of vanadium in the vanadium pyrochlore yellow pigment by electron spectroscopy by chemical analysis and electron spin resonance showed that the oxidation state of vanadium was V^{5+} and its yellow color mostly originated from V^{5+} substituted for Ti^{4+} [10, 11].

XRD (X-Ray Diffraction) results (Fig. 6a) indicate the crystallization of $\text{Y}_2\text{Sn}_2\text{O}_7$ as the only crystalline phase in all samples except in $x = 0.32$ that shows very weak peaks associated to YVO_4 along with perovskite peaks. Spectral and color rendering of samples by UV-Vis-NIR reflectance diffuse spectroscopy (Fig. 6b) shows a sharp band centered at 250 nm associated to the $\text{Sn}^{4+}-\text{O}^{2-}$ band transfer and an additional band centered at 500 nm responsible of yellow color and associated to $\text{V}^{5+}-\text{O}^{2-}$ band transfer. The maximum of absorbance is observed for $x = 0.16$ sample. CIEL*a*b* results summarized in Table 1 indicate that the yellow b^* parameter increases with x until $x = 0.16$ and decreases for $x = 0.32$ indicating a solubility limit of vanadium in this pigment around $x = 0.16$. The enameled powders were 5 w%. glazed in a CaO-ZnO-SiO_2 (1,080 °C) single firing glaze but do not produce color; in $\text{Na}_2\text{O-CaO-PbO-SiO}_2$ (1,000 °C) double

Pigment, Ceramic, Table 1 CIEL a*b* colorimetric coordinates for the $\text{Ca}_x\text{Y}_{2-x}\text{V}_x\text{Sn}_{2-x}\text{O}_7$ yellow pigments

Sample (x)	L*	a*	b*
0.04	84.3	1.2	26.6
0.08	87.2	0.2	30.8

0.32	85.8	0.8	33.5

firing glaze, the color of all samples is similar (CIEL*a*b* = 78/5/35) (Fig. 6d).

In order to increase the reactivity of the system, the ceramic optimized composition $x = 0.16$ was prepared by ammonia coprecipitation (CO) and Pechini route (CI). In both routes Y ($\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$, $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$, and $\text{VOSO}_4 \cdot 8\text{H}_2\text{O}$ (ALDRICH) were used as precursors. In the CO route the precursors were solved in water (250 ml for 5 g of final product), then concentrated ammonia was dropped at 70 °C in continuous stirring until pH = 8; finally powder was obtained by drying in oven at 110 °C. In CI route, a molar ratio metallic cations/ethylene glycol/citric acid = 1:1:1 was used. Firstly precursors were solved in water (250 ml for 5 g of final product) and citric acid was solved at 70 °C in vigorous stirring, and then ethylene glycol was added and maintained 8 h for esterification. The obtained ester was dried at 110 °C and submitted to charring treatment at 250 °C. Na_2SiF_6 flux agent was added to CO or CI powders by manual mixture in an agatha mortar using acetone media. XRD results obtained at 1,000 °C/6 h for both CI and CE show peaks associated to pyrochlore along with unreacted SnO_2 and Y_2O_3 peaks; CO sample only shows weak peaks associated to SnO_2 along with pyrochlore. At 1,200 °C all samples show pyrochlore as the only crystalline phase detected. CO at 1,200 °C shows the best pigmenting results in double firing glaze ($L^*a^*b^* = 80.0/5.0/43.7$) than CE (79.3/2.6/35.4) and CI (81.7/0.1/31.8).

SEM micrographs of powders fired at 1,200 °C indicate the presence of aggregates of sub-micrometric particles in all samples (Fig. 6c). Size of aggregates in CE and CO sample (2–6 μm) is similar but more compact in CO sample and higher than in citrate powder

(1–4 μm). Also size of particles forming aggregates is higher for CE (500 nm) than for CO (300 nm) and higher than CI powder (150 nm). Likewise SEM-EDX (Scanning Electron Microscopy-Energy Dispersive X-Ray Spectroscopy) microstructural analysis of powders fired at 1,200 °C (not shown) indicates that codopants, vanadium, and calcium present a homogeneous distribution on samples. However the global content of calcium is higher than vanadium, probably due to vanadium evaporation during firing. Likewise the content of vanadium is slightly higher in CO and CE sample than in CI sample in agreement with color intensity observed on glazed samples.

Environmental Safety: Ecotoxicity Evaluation

The environmental safety using ceramic pigments is an important limitation that gives the severe regulation of toxic components such as lead or cadmium. It is necessary to check the safety of the pigments. The leaching test is usually used for determining the ecotoxicity of solids. For example, the European leaching test was performed at a ratio of liquid to solid sample $L/S = 16 \text{ L/kg}$. A mixture of 10 g solid sample and 160 mL distilled water was combined in borosilicate glass bottles and then agitated for 24 h at 10 rpm with a rotary agitator. The leachate was then collected by filtration through a 0.45 μm membrane filter. The toxicity of the leachates is evaluated using a battery of bioassays including the photobacterium *Vibrio fischeri* or *Photobacter phosphoreum* (Microtox test) and the crustaceans *Daphnia magna*. Microtox test was based on the bioluminescence measurement of the marine bacteria *V. fischeri*, within exposure time to leachates of 15 min., using the DeltaTox PS1 Analyzer.

The Microtox ecotoxicity test results for the above-discussed pigments are shown in Tables 2 and 3. In the case of the yellow of the pyrochlore $\text{Ca}_{0.16}\text{Y}_{1.84}\text{V}_{0.16}\text{Sn}_{1.84}\text{O}_7$, both unmineralized ceramic CE and sonocoprecipitated SONO powders fired at 1,200 °C/6 h are compared in Table 2.

Pigment, Ceramic, Table 2 EC50 Microtox results for pyrochlore of tin pigments

Sample	EC50 (ppm)
$\text{Ca}_{0.16}\text{Y}_{1.84}\text{V}_{0.16}\text{Sn}_{1.84}\text{O}_7$ CE 1,200 °C/6 h)	296,400
$\text{Ca}_{0.16}\text{Y}_{1.84}\text{V}_{0.16}\text{Sn}_{1.84}\text{O}_7$ SONO 1,200 °C/6 h	65,639

Pigment, Ceramic, Table 3 EC50 Microtox results for perovskite of neodymium pigments

Sample	EC50 (ppm)
FeNdO₃	86,664
2 %BaF ₂ +8%MgF ₂	
SONO fired at 1,100 °C/3 h	
CrNdO₃	54,398
2 %BaF ₂ +8%MgF ₂	
SONO fired at 1,100 °C/3 h	
(Mg_{0.5}Fe_{0.5})(Co_{0.5}Fe_{1.4}Cr_{0.1})O₄	2,336
SONO fired at 1,000 °C/3 h	

In the SONO method, the chloride precursors were dissolved in water/diethylene glycol = 1:1 v/v media and were coprecipitated in ultrasonic bath by dropping 12% ammonia solution until $\text{pH} = 8$. In agreement to European laws, the limit of EC50 (equivalent concentration of leached that decreases the bioluminescence of *V. fischeri* to 50%) is 3,000 ppm. Therefore the pigment accomplishes the European regulations.

In the case of the yellow of the neodymiums above described (violet of FeNdO₃ with 2% BaF₂+8%MgF₂ SONO fired at 1,100 °C/3 h and black of CrNdO₃ with 2%BaF₂+8%MgF₂SONO fired at 1,100 °C/3 h), the Microtox results are compared with the reference black of spinel (Mg_{0.5}Fe_{0.5})(Co_{0.5}Fe_{1.4}Cr_{0.1})O₄ SONO fired at 1,000 °C/3 h) in Table 3. In agreement with European limit of EC50 the perovskite of neodymium pigments accomplish the European regulations but not the spinel black due to released chromium. The pigments based on rare-earth components usually give eco-friendly pigments [12].

UK

Definition

A pigment is a finely divided solid, crystalline coloring material, manufactured in a finely divided form, and is essentially insoluble in its application medium [1, 2]. Pigments are classified chemically as either organic or inorganic [1–3]. The requirement for organic pigments to be insoluble distinguishes them from organic dyes which are generally required to be soluble, especially in water for textile coloration. Organic pigments are used mainly in the coloration of paints (coatings), printing inks and plastics and, to a certain extent, in a wider range of substrates, including paper, textiles, rubber and cosmetics. Their application generally involves incorporation into a liquid medium, for example a wet paint, ink or a molten thermoplastic, using a dispersion process in which clusters of pigment particles are broken down into primary

Robert Christie has retired.

particles and small aggregates. The pigmented medium then solidifies, by physical solidification, solvent evaporation or polymerization, and the finely divided pigment particles become fixed mechanically in the solid matrix.

Properties

Optical Properties

Organic pigments are used to modify the optical properties of a material into which it is incorporated. The most obvious effect is to provide the desired color. The color provided by an organic pigment is primarily dependent on its molecular structure. However, two further factors influence their color since they are used as solid, crystalline particles: the crystal structure, i.e., the way in which the molecules pack in their crystal lattice, and the particle structure, notably particle size and shape distribution [4]. Organic pigments generally provide bright, intense colors and in this sense offer advantage over their inorganic counterparts. Their color strength increases with a decrease in particle size, so for optimum color strength they are commonly manufactured at as small a particle size as possible, approaching the nanometer range.

However, providing color is not their only optical function. They may also be required to provide opacity. This feature is most important in paints which are commonly designed to obscure the surface to which they are applied. Alternatively, and in complete contrast, high transparency may be important. For example, multicolor printing generally uses inks of four colors, the three subtractive primaries, yellow, magenta and cyan, together with black, and transparency is essential to ensure that subsequently printed colors do not obscure the optical effect of the colors printed previously.

Fastness Properties (Technical Performance)

Organic pigments must be capable of withstanding the effects of their environment, both during processing and in their anticipated useful lifetimes. They are required to be fast to light, weathering (if external exposure is envisaged),

heat and chemicals (such as acids and alkalis) to a degree dependent on the demands of the application. Pigments are also required to show solvent resistance, which refers to their ability to resist dissolving in solvents that they may contact in their application, in order to minimize issues such as 'bleeding' and migration of color. Heat stability is critically important in pigments for applications which require processing at high temperatures and is thus a vital factor in the coloration of thermoplastics. The level of thermal stability required depends on the processing temperature for the polymer in question and on the time of exposure.

Dispersibility

It is essential that an organic pigment is well dispersed into its application medium, for example during its introduction into a paint, printing ink or plastic article. Pigment powders consist of clusters of aggregated particles which are subjected to conditions which break down large aggregates into smaller aggregates and primary particles to the degree required to give the optimum properties. *Dispersibility* refers to the ease with which the desired level of dispersion is achieved.

Classification of Organic Pigments

Classification According to Technical Performance

Organic pigments may be classified broadly as classical or high performance (Fig. 1). Organic pigments were developed in the late nineteenth century as synthetic textile dyes became established. Many early organic pigments were based on water-soluble dyes rendered insoluble by precipitation onto colorless inorganic substrates, such as alumina and barium sulfate. These products were referred to as *lakes*. A significant early development was the introduction of a range of azo pigments, which provide the basis for the most important yellow, orange and red organic pigments currently in use. These so-called classical azo pigments offer bright, intense colors, although only moderate

Pigments, Organic,
Fig. 1 Organic Pigment
Classification

performance in terms of fastness properties. A critical historical event was the discovery, in 1928, of copper phthalocyanine. This blue pigment was the first product to offer the outstanding intensity and brightness of color that is typical of organic pigments, combined with an excellent set of fastness properties. The discovery stimulated the quest for other chemical types of organic pigment which could emulate the high performance properties of copper phthalocyanine in the yellow, orange, red and violet shade areas, an activity that gained further impetus from the growth of applications that demand high levels of technical performance, such as automotive paints and the plastics and synthetic fiber industries [4].

Classification According to Chemical Structure

The broad chemical classes encountered in industrial organic pigments are shown in Fig. 1, which also illustrates their relationships with the classical and high-performance classifications.

Product Overview

This section provides an overview of the characteristic structural features of the important chemical types of commercial organic pigments, together with a discussion of how these structural features determine their suitability for particular applications. Structure-property relationships in organic pigments are complicated by the dependence of color and technical performance not only on the molecular structure but also on the solid-state crystal structural arrangement and on the size

and shape distribution of the pigment particles [5]. Classical organic pigments are commonly prepared in as fine a particle size as is technically feasible in order to give maximum color strength and brightness and transparency, a combination that means that organic pigments are especially well suited to printing ink applications, where the particle size is commonly below 0.05 μm . For some applications, notably surface coatings, a larger particle size is desirable for improved opacity and fastness properties, but this is achieved at the expense of color strength. Organic pigments are unable to provide the degree of opacity that is typical of inorganic pigments, because of the lower refractive index associated with organic crystals. With organic pigments, there is an optimum size for opacity, often in the range 0.2–0.4 μm .

Commercial organic pigments exhibit a rather variable set of fastness properties, dependent on both the molecular structure and on the nature of the intermolecular association in the crystalline solid state. Since organic molecules commonly exhibit some tendency to dissolve in organic solvents, structural features are incorporated that enhance solvent resistance, by enhancing the strength of intermolecular interactions within the crystal structures. For example, an increase in the molecular size of the pigment generally improves solvent resistance. Hydrogen bonding is a highly important feature in organic pigment structures, promoting enhanced stability (e.g., to light and heat), and insolubility, as demonstrated in the numerous specific chemical structures presented in Figs. 2, 3, 4, 6 and 7 later in this section. Of particular importance in this respect is the

Pigments, Organic, Fig. 4 Intermolecular association in benzimidazolone azo pigments

amide (-NHCO-) group which features prominently in the chemical structures of organic pigments as a result of its ability to participate in strong hydrogen-bonding, both intramolecular and intermolecular. A related structural feature is found in certain pigments which contain N-H and

C=O groups in ring systems, an arrangement that leads to similar high technical performance as a result of strengthening the intermolecular association throughout the crystal structure. Examples of such arrangements can be found in Figs. 4 and 7. The incorporation of halogen substituents

7:1 Pigment Blue 15 (CuPc)

Pigments, Organic, Fig. 5 The structure of copper phthalocyanine

and of metal ions, particularly alkaline earths and transition elements, can also have a beneficial effect on fastness properties.

Azo Pigments

Azo pigments dominate the yellow, orange and red shade areas in commercial organic pigments [6]. The chemical structures of some important classical azo pigments are shown in Fig. 2. Many texts follow the convention to illustrate the structures in the azo tautomeric form. In this text, however, the structures are illustrated as ketohydrazones, since structural studies of industrial azo pigments have demonstrated that the pigments exist exclusively in this form in the solid state [1, 2, 5, 6]. Simple classical monoazo pigments such as Hansa Yellow G (**1**) and Tolidine Red (**2**) are products that provide bright colors and good lightfastness, but inferior solvent

Pigments, Organic, Fig. 6 The structures of selected carbonyl pigments

Pigments, Organic,
Fig. 7 Intermolecular
 association in the crystal
 structure of quinacridone (9)

resistance. The good lightfastness is attributed to the stability provided by the intramolecular hydrogen-bonding in six-membered rings. The inferior fastness to organic solvents is due to their small molecular size and intermolecular interactions in the crystal structures involving essentially only weak dipolar and van der Waals' forces. The use of these pigments is largely restricted to decorative paints since the pigments resist dissolving in the solvents used (water or aliphatic hydrocarbons) at the low temperatures involved in these applications. The most important yellow and orange azo pigments, particularly for printing inks are disazo pigments (diarylides),

exemplified by compounds **3a-3c**. They exhibit higher color strength and transparency than the corresponding monoazo pigments, properties particularly suitable for printing inks, and improved solvent fastness, attributable to the larger molecular size. The most important classical red azo pigments are metal salts, such as compounds **4a-4c**, derived from azo dyes containing $\text{-SO}_3^-\text{Na}^+$ or $\text{-CO}_2^-\text{Na}^+$ groups by replacement of the Na^+ ions with divalent metal ions, notably Ca^{2+} , Sr^{2+} , Ba^{2+} and Mn^{2+} [7]. They are products of high color strength and brightness, high transparency and good solvent resistance. CI Pigment Red 57:1, **4a**, is the pigment principally used to

provide magenta inks for multicolor printing. These products are complex structurally [8]. In the crystal structure, the metal atoms bond to carboxylate, keto and sulfonate oxygen atoms and to water molecules, with intermolecular bridging leading to a polymeric ladder structure.

There are two classes of high-performance azo pigments: disazo condensation pigments and benzimidazolone azo pigments. The chemical structures of representative examples of these products are illustrated in Fig. 3. Disazo condensation pigments constitute a range of durable yellow, red, violet and brown products, with structures such as compound **5** (CI Pigment Red 166). These pigments derive their name, from the elaborate synthetic procedures involved in their manufacture, which involves a condensation reaction. A second group of high-performance azo pigments contain the benzimidazolone group, exemplified by CI Pigment Red 183, **6**, which range in shades from yellow to bluish-red and brown and exhibit excellent fastness properties. Their high stability to light and heat and their insolubility is attributed to extensive intermolecular association as a result of hydrogen-bonding and dipolar forces in the crystal structure, as illustrated in Fig. 4.

Copper Phthalocyanines

Copper phthalocyanines provide by far the most important of all blue and green pigments [9]. Copper phthalocyanine, **7** (CuPc, CI Pigment Blue 15; Fig. 5), is arguably the single most important organic pigment. Although generally regarded as a classical organic pigment, it could equally well be described as a high-performance organic pigment. It finds widespread use in most pigment applications because of its brilliant blue color and its excellent resistance towards light, heat, solvents, acids and alkalis. In addition, copper phthalocyanine is relatively inexpensive as it is manufactured in high yield from low cost starting materials. CuPc exhibits polymorphism, referring to the ability to exist in different crystal forms. Both the reddish-blue α - and greenish-blue β -forms are of commercial importance. The β -form of the pigment is almost always the pigment of choice for cyan printing inks, and it is

suitable also for use in many paint and plastics applications. The most important green organic pigments are halogenated copper phthalocyanines, CI Pigment Green 7, in which the 16 ring hydrogen atoms of the CuPc molecule are replaced virtually completely by chlorine, and CI Pigment Green 36, a designation which incorporates a range of bromo- and bromochloro-copper phthalocyanines. The phthalocyanine greens exhibit the same outstanding color and technical performance as the blue pigments and find equally widespread use in the coloration of paints, printing inks and plastics.

Cationic Dye Complex Pigments

These bright, intensely colored organic pigments are derived from selected basic (cationic) dyes rendered insoluble by associating with large counteranions, such as phosphomolybdotungstates. They are especially important as violet, blue and green pigments for printing inks.

Carbonyl Pigments

Carbonyl colorants (Fig. 6) contain the carbonyl (C=O) group as the essential structural component and chromophore [10]. A wide variety of structural types have been developed to provide yellow, orange, red and violet shades with the high-performance properties comparable with those of copper phthalocyanine blue and green pigments. A number of vat dyes for textile applications, after conversion to an appropriate pigmentary physical form, are suitable for use in many paint and plastics applications [10]. Examples of these so-called vat pigments include anthraquinones, such as Indanthrone Blue, **8** (CI Pigment Blue 60). Other high performance carbonyl pigments include quinacridone, **9** (CI Pigment Violet 19), diketopyrrolopyrrole (DPP) pigments, such as CI Pigment Red 254, **10**, and isoindoline CI Pigment Yellow 139, **11**. The excellent lightfastness, solvent resistance and thermal stability of carbonyl pigments may be explained in many cases by intermolecular association in the solid state as a result of a combination of hydrogen bonding and dipolar forces. A diagrammatic illustration of the intermolecular hydrogen bonding which exists in the crystal

lattice arrangement of the quinacridone, **9** is given in Fig. 7 [11].

Dioxazines

The dioxazine, **12** (Carbazole Violet), whose polycyclic structure is shown in Fig. 8, is an important violet high-performance organic pigment.

Manufacture

The process by which a pigment is manufactured may be considered as involving a series of stages as shown in Fig. 9. The first of these is *synthesis*, the sequence of chemical reactions which form the pigment molecules. This is illustrated later for azo and copper phthalocyanine pigments. However, simply carrying out this chemistry does not necessarily give the product in a form that is optimum for a particular application. In a second phase, commonly referred to as *conditioning*, the product is developed into an appropriate crystalline form, with a controlled particle size and shape distribution, and the surfaces of the particles may be modified by suitable treatments. Depending on the pigment, these two stages may

be separate or combined into a single process. An important reason for surface treatment is to enhance the dispersibility of a pigment as it is introduced into a paint, printing ink or plastic article. In the dispersion process, clusters of aggregated particles are subjected to conditions which break down large aggregates into small aggregates and primary particles to the level required to give the optimum optical properties. The nature of the surfaces of pigment particles is of importance in their application performance because it is these surfaces that are in contact with the application medium. The particle surfaces formed during the synthesis of organic pigments often have highly polar character and may show poor compatibility with many of the non-polar (hydrophobic) organic media used in the applications. The pigments are therefore often treated with materials such as organic surface-active agents or resins to change the nature of the particle surfaces. In the treatment of the pigment with a surface-active agent, which contains separate hydrophilic and hydrophobic regions, hydrophilic groups attach to a polar pigment surface and hence the pigment effectively acquires a new surface which is hydrophobic and more compatible with an organic application medium. This

Pigments, Organic, Fig. 10 Synthesis of monoazo and (symmetrical) disazo pigments

surface also presents a barrier so that the pigment particles are less susceptible to aggregation, and those aggregates that are formed are more easily broken down by the dispersion process. Finally, the pigment is subjected to *finishing* whereby it is converted into a form acceptable to the user, for example by grinding to a fine powder or incorporating into a concentrated dispersion. The conditions of synthesis of those organic pigments prepared by precipitation from reaction in water are commonly controlled to ensure that they are formed directly in an appropriate particle size range. Commonly, they precipitate in a poorly-defined crystal form, and so are subsequently treated at elevated temperatures, for example in the presence or absence of solvents, water in the case of classical azo pigments or organic solvents in the case of high-performance pigments, in order to develop high crystallinity and ensure that the products show optimum optical properties. Some high-performance organic pigments, synthesized at high temperatures in organic solvents, are produced initially in a large particle size form, which must be reduced to a fine particle size to make them useful pigmentary products.

As illustrated in Fig. 10(a), monoazo pigments, such as products (1) and (2) are manufactured using the two-stage process of diazotization, by treatment of a primary aromatic amine with sodium nitrite in an aqueous acidic medium cooled with ice, followed by azo coupling of the resulting diazonium salt with an appropriate coupling component [6]. To ensure that the pigments are obtained in high yield and purity, it is essential

to maintain careful control of experimental conditions to minimize the formation of side products which might adversely affect the color and performance of the pigments. When azo coupling is complete, the aqueous suspension is usually heated to the boil for a period of time, often in the presence of surface-active agents, to refine the pigment particles and develop crystallinity. Diarylide pigments such as compounds (**3a-3c**) are derived synthetically from bis-diazotization of an aromatic diamine which is subsequently coupled with two moles of coupling component as shown in Fig. 10(b). Metal salt azo pigments, such as compounds (**4a-4c**) are prepared by traditional diazotization/coupling processes to form the sodium salt of an azo dye which is treated with a solution of a salt of the divalent metal to displace the sodium and form the insoluble pigment.

Although the structure of copper phthalocyanine is rather complex, its synthesis is remarkably straightforward. It may be prepared in virtually quantitative yield from readily available, low cost starting materials [9]. In the most important method, as illustrated in Fig. 11, phthalic anhydride is heated with urea, the source of nitrogen in the process, copper (I) chloride and a catalytic amount of ammonium molybdate at around 200 °C in a high boiling organic solvent. This process produces crude copper phthalocyanine as large particles, which require to be reduced in size, for example by milling in the presence of inorganic salts. Carbonyl and dioxazine high-performance pigments tend to have diverse and

Pigments, Organic,**Fig. 11** Synthesis of Copper phthalocyanine

individualized manufacturing routes, details of which can be found elsewhere [10].

Current and Future Developments in Organic Pigments: A Brief Overview

Recent decades have seen major changes in the organic pigment manufacturing industry. Manufacturing capacity has declined substantially in the traditional heartlands of Europe and the USA where the original discoveries took place and the products and processes were developed. This has been accompanied by rapid growth of the industry in Asia, mainly in China and India. The industry currently produces a mature range of products for conventional applications as the cost of introducing new products to the market has become increasingly prohibitive, not only in terms of R&D effort but also in addressing the demands of toxicological evaluation and environmental legislation. Opportunities have been presented by the emergence of a range of applications in new technologies, demanding new types of organic colorant referred to as functional dyes and pigments, or as π -functional materials. Organic pigments have been developed or modified for use in reprographic techniques, such as electrophotography and digital inkjet printing, and in electronic display technologies. Addressing environmental issues has become a high priority. It is reasonably reassuring that organic pigments themselves are generally considered to be of low toxicity because of their high insolubility. However, there are a few concerns about trace amounts of toxic by-products formed in their manufacture or application. For example, diarylide pigments are no longer recommended for high-temperature applications on the basis of

evidence that they may cleave thermally releasing the highly toxic starting material 3,3'-dichlorobenzidine (DCB) [12]. Certain azo pigments also have the potential to form polychlorobiphenyls (PCBs) during their manufacture [13].

Polychromy

José Luis Caivano
Secretaria de Investigaciones FADU-UBA,
Universidad de Buenos Aires, and Conicet,
Buenos Aires, Argentina

Definition

Polychromy refers to the combination of many colors in a visual scene, whether it is a natural landscape or a man-made arrangement of things, for instance, a piece of art, a design, an object, a building, an urban landscape, etc. The word is

formed by the Greek words *poly* (many) and *chroma* (color).

Overview

Colors can be divided into two separate classes: *chromatic colors* (such as red, green, blue, yellow, and any other tone), and *achromatic colors* (such as white, black, and grays). The characteristic of chromatic colors is that they have a definite hue, in addition to a certain saturation and lightness. Achromatic colors do not have a definite hue, and their saturation has a zero value; they are only distinguished by their lightness. When many chromatic colors of different hue appear together, this is called a *polychromatic* composition. Generally, more than two (at least three) colors of different hue are needed to properly speak of polychromy. The usual terminology differentiates *monochromy* (one color), *dichromy* (two colors), and *polychromy* (more than two colors) [1]. But sometimes the terms *trichromy* and *tetrachromy* may be employed, and thus, in this case, polychromy is applied to more than four colors ([2], pp. 279–280). If a composition uses colors of different saturation and lightness but of the same hue (for instance, different kinds of yellow that could be lighter or darker and more or less saturated), then this arrangement is said to be a *monochromatic* color composition or a monochrome arrangement (*mono*: one; *chroma*: color). If a composition uses only gray colors of different lightness (which may also include black and white), it is called an *achromatic* composition.

While it may seem from the Greek etymology that the words *color* and *chroma* are equivalent, modern conceptions make a distinction between them. *Color* refers to a visual sensation in general, which includes not only the categories of red, green, blue, yellow, etc. but also gray, black, and white. The term *hue* is used more specifically to name the quality of a chromatic color that makes yellow look different to red, red to green, green to blue, etc. In opposition, gray colors, black, and white have no hue. In modern usage, *chroma* is considered a synonym of saturation, i.e., the strength, the colorfulness, or the degree of purity

of a certain hue. As previously said, gray colors, black, and white have no chroma (saturation), or have chroma zero. However, in order to avoid confusion with the original Greek etymological meaning (chroma = color), the term *saturation* is recommended, rather than *chroma*.

Then, it has to be taken into account that the word *color* is often used with two different semantic extensions: with a narrow sense, meaning “chromatic color,” and with a wide sense, including also grays, white, and black as color sensations. The narrow meaning is evident when some people say that black is not a color (because it is considered “the absence of color”), white is not a color (because it is “the sum of all colors”), and grays are not colors either. From a more comprehensive point of view, and in modern usage, this is a misconception.

All the previous clarifications are important in order to understand that *polychromy* means not just “many colors” but many chromatic colors of different hue. Polychrome compositions may include, of course, achromatic colors, but their presence must be accompanied by chromatic colors of different hue in order to be truly polychromatic.

Polychromy in Color Harmony

From the quantity of hues that take part in a color combination, Antal Nemcsics states five types of color harmonies ([2], pp. 274–280):

- *Monochrome harmonies*, with colors taken from the same hue section in a color order system.
- *Dichrome harmonies*, with colors taken from two sections of hue, preferably complementary hues.
- *Trichrome harmonies*, with colors taken from three different hues, which may be evenly spaced in the whole chromatic circle or grouped forming a domain in one sector of it.
- *Tetrachrome harmonies*, with colors taken according to regular series from four hue triangles, which may be in four well-separated domains in the chromatic circle, in only one

domain, in a group of three hues in one domain against one hue opposite to them, or in two complementary pairs.

- *Polychrome harmonies*, with colors belonging to more than four different hues, preferably making groups of hues in definite domains.

Polychromatic Compositions Along History

The use of polychromy in the visual arts, decoration, and architecture has a long history. The small book by Thomas Goodwin reviews some of the earlier examples and concentrates mainly around the Middle Ages and the religious architecture in England [3]. Goodwin starts the introduction with a definition and then refers to the practice of polychromy in Egypt, Persia, and other antique civilizations:

The art of decorating the interiors of buildings with colour and gilding—Polychromy, as it is sometimes called, — is one which has been practised in all ages and among all nations. Its universal use among all people, as well barbarous as refined, is a satisfactory proof that it is founded upon the best and most natural principles. ([3], p. 1)

The Greeks painted their temples and family dwellings with many vivid colors of different hue, such as red, yellow, and blue. The idea that Greek temples had just the appearance given by white marble has been superseded long time ago, even when for some people it is still a novelty. Greeks started making wooden temples, and of course they painted them not only for decorative reasons but also to protect the wood. This usage created a style, and centuries later in the Greek culture and artistic practice, when the wood was replaced by marble for building temples, the custom of using colors applied by paints remained. And then, Greeks painted over the marble, producing a polychromatic architecture. The painted colors faded with time, the pigments disappeared, and for centuries the buildings remained as ruins of white marble for the later generations.

By the middle of the nineteenth century, Jacques-Ignace Hittorff succeeded in conveying the attention toward the discovery, made

Polychromy, Fig. 1 Two Greek sculptures

(c.490 BC): An archer from the Temple of Aphaia in Aegina, and a rider from the Acropolis in Athens. Present condition of the sculptures (left) and the polychrome reconstruction, as shown in the exhibition *Gods in color*, see <https://buntegoetter.liebieghaus.de/en/>

previously to him but neglected for many years, that the Greek architecture was not white – as it was believed for centuries based on the color of the ruins. It was polychromatic. Hittorff published these findings in his book of 1851 on the polychromy of Greek architecture, where he made a case of the temple of Empedocles in Selinus, Sicily [4]. The more general acceptance of this evidence came to change a long-held view about the Greek sense of beauty and harmony. However, it took some time to change the traditional notion, and the neoclassicist architects of the nineteenth century continued to make neoclassic buildings (based on the orders of Greek architecture) in gray, white, or with a monochromatic appearance. As a practicing architect, Hittorff was an exception, since he made polychromatic buildings [5].

Polychromy was also present in statuary in antique Greece. At the beginning of the nineteenth century, Quatremère de Quincy presented a detailed essay on the taste for polychrome sculpture among Greeks and Romans [6]. More recent

studies provide additional evidence that Greek artists used to paint with referential colors the marble statues, imitating the colors of skin, hair, representing the colors of clothes, etc. (Fig. 1). The analysis by Manzelli starts from the first studies on the polychromy of Greek and Roman sculptures, goes through the pigments and painting techniques of statues, and comes to consider the symbolic meanings of color in the ancient classical culture [7]. Since the turn of the third millennium, the research on the coloration of classical statues has been acquiring new interest, particularly with the exhibition at the Munich Glyptothek in 2003, and with the increasing number of publications on the subject during the past two decades [8].

Roman culture inherited the practice of polychromy from the Greeks and applied it also to statuary and architecture. In the present times, there is still physical evidence of the polychromy used in the interior of houses and buildings in the old Roman city of Pompeii, which remained

Polychromy, Fig. 2 Rose window in Notre Dame, Paris (left), and projected lights that recreate the original polychromatic appearance of the Amiens cathedral (right)

preserved for centuries under the ashes of the Vesuvius volcano.

There are evidences that the first Christians decorated the catacombs with color. This practice naturally continued with the first Paleochristian churches and during the Romanic style, and acquired a high degree of perfection in the Byzantine period, particularly with the mosaics. This technique of using polychromy has made it possible to preserve beautiful abstract decorations and figurative representations for more than a thousand years, up to the present days.

During the Middle Ages the polychromy in architecture was particularly prominent in the stained glass windows of the cathedrals. The colored windows also remained until now without deterioration. But, even when it is not always visible today, because pigments have faded, the interior of Gothic cathedrals exhibited architectural elements, such as columns and arches, painted in many colors, in addition to polychrome sculptures. What seems more surprising, from recent discoveries, is that not only the interior spaces but also the facades of many Gothic

cathedrals were painted with polychromatic combinations. A restoration of the western facade of the Amiens cathedral made in the 1990s revealed that it was originally painted in various colors and that by the thirteenth century it had a polychromatic appearance (Fig. 2).

In the Renaissance, most of the practice of polychromy applied directly on structural or decorative elements of architecture started to be neglected, and was partially replaced by representative frescoes and paintings on the walls and ceilings that endorsed architectonic spaces with color and images “borrowed” from the art of painting. According to Leon Solon, it was in this period that color began to be avoided and disassociated from architecture ([9], pp. 9–10). Even when the Renaissance implicated a classical revival, at this time, around the fifteenth century, very little or nothing was known about the polychromy of the Roman and Greek classical architecture, because the only remnants were achromatic or monochromatic ruins, and archeological studies had to wait until the nineteenth century to flourish. However, evidence of

polychromatic architecture of the medieval churches was supposedly present in the fifteenth century, but since the Renaissance was also a strong reaction against the Gothic style, this may have been another reason for abandoning color. Solon presents various other reasons and makes some speculations about this feature of Renaissance architecture ([9], pp. 11–15).

Owen Jones and Gottfried Semper were two nineteenth-century architects who deserve a special mention due to their contributions to the study of polychromatic architecture. In 1852, Jones published *An Attempt to Define the Principles which Should Regulate the Employment of Colour in the Decorative Arts*, in which he makes 22 propositions or rules for the use of color [10]. Jones was also responsible for coloring a Greek monument exhibited in the Crystal Palace, and he did this task based upon the researches of his time. In a book published in 1854, he explains and defends the criteria with which he selected and applied colors to the different parts of the monument [11]. An appendix of the book includes a fragment written by Gottfried Semper on the origin of polychromy, reviewing cultures such as Indians, Jews and Phoenicians, Greeks, Assyrians, Persians, Egyptians, Chinese, etc. Semper sets forth the hypothesis that this origin relies in textiles, which constitute the oldest manufactures used as covering, shelters, fences, or partitions of space in most cultures. Since textiles were usually dyed in many colors, it is supposed that this practice moved in a natural way to architecture, when textiles were replaced by strongest materials in order to build living spaces ([11], pp. 47–53). *The Grammar of Ornament*, published by Jones in 1856, constitutes an extraordinary source of historical color designs, systematically arranged and covering different geographies and periods, from the ancient times to the early seventeenth century [12].

Another source of information on polychromatic decoration, in this case concentrated on the medieval-style architecture, and particularly on the Gothic revival and Victorian style of the nineteenth century in England, is the book published in 1882 by the Scottish architects and brothers

George and William Audsley, with plenty of illustrations in the form of colored plates [13].

Architectural Polychromy in the Twentieth Century

The Case of Le Corbusier

Without any doubt, the richest and most complex personality of twentieth-century architecture has been Le Corbusier (Charles Edouard Jeanneret). His relationship with color has been complex too, and sometimes contradictory [5]. Between Bruno Taut, uncompromising defender and propagandist of polychrome architecture, and Walter Gropius, who theorizes about color but in his works uses it in extremely moderate doses, Le Corbusier appears to be midway. Precisely, he maintains some differences with Taut regarding color. About the chromatic audacity of Taut, Le Corbusier goes on to say, “My God, Taut is color blind!”

The early writings about color of Le Corbusier were published in the articles on purism and cubism in the journal *L'Esprit Nouveau*, in collaboration with the painter Amédée Ozenfant. An article from 1918 reads,

The idea of form precedes that of color. The form is preeminent, color is but one of its accessories. Color depends entirely of the material shape: the concept of sphere, for instance, precedes the concept of color; it is conceived as a colorless sphere, a colorless plane, color is not conceived independently of some support. Color is coordinated with form, but the reciprocal is not true. ([14], p. 42)

Some other articles published in 1921, 1923, and 1924 in the same journal proceed more or less in the same vein, that is, denying any importance that color might have in the construction of space in painting [15]. The curious fact is that a few years later, in his writings on architectural polychromy of 1931, Le Corbusier seems to have changed his mind completely, to the extent of quoting and agreeing with Fernand Léger, who said, “Man needs colors to live, it is an element as necessary as water and fire.” In addition, Le Corbusier describes examples of his own use of color in order to drastically change the spatial

perception of architecture, as in the neighborhood designed and built in Pessac [16].

In his monograph written for the exhibition of the *Pavillon des Temps Nouveaux*, Le Corbusier includes a chapter entitled “Polychromy = Joy,” in which he associates the creative ages of architecture with the vitality of chromatic color and relates the stagnant academicism to sad gray ([17], pp. 22–23). It seems that in both his theories and his works, Le Corbusier evolved toward a more conscious and thorough consideration of the power that color has to modify the spatial environment. This is especially evident in the buildings projected and built after World War II, in what is called his “brutalist” period.

As with the works by other architects of the modern movement, Le Corbusier’s architecture (which was reproduced in black-and-white photography in its time) is being reconsidered in the light of recent restorations and studies. The *Ville Savoye*, a paradigm of modern architecture of the 1920s and 1930s, was not white (as it appeared in many publications) but developed a complex polychromatic Scheme [18].

Le Corbusier’s text on architectural polychromy, written in the 1930s, remained as an unpublished manuscript. The first edition of this text, including also the color collections produced for the Salubra wallpaper company, was edited by Arthur Rüegg and published in 1997 [16, 19]. As for the polychromy in the purist architecture of Le

Corbusier, and his evolution, see also the book by Jan De Heer [20].

Polychromy in Modern Architecture and Beyond

Apart from the particular case of Le Corbusier, there are many other examples of polychromy in architecture in the twentieth century. At the beginning of the century, the Art Nouveau and Art Deco styles were particularly profuse with colors. The Neoplasticist movement is recognized by the use of pigmentary primary colors red, yellow, and blue in high saturation and combined with black and white in different spatial planes. The best examples of Neoplasticist architecture and design can be found in the works by Gerrit Rietveld (Fig. 3). The followers of the organicist architecture (whose paradigm is Frank Lloyd Wright), supporters of not covering surfaces with paints but leaving the materials to express their inherent color, were not less aware of the value of color. Perhaps with the aim of providing a rich polychromy without using paints, Wright made a plentiful use of stained glass windows, as a way of “painting” with light.

The main idea behind the polychromy of modern architecture is that color is not used with a decorative purpose. Instead, it should appear to enhance or modify the space, to express functions,

Polychromy, Fig. 3 G. Rietveld: Façade and interior of the Schröder house, Utrecht, The Netherlands, 1924

or to differentiate materials or construction elements. Within some architectural trends or contexts of the modern movement it was evident already in the early 1960s that color entailed new solutions but also new problems. It is for this reason that the Scientific and Technical Center for Building (Centre Scientifique et Technique du Batiment) in France organized a seminar on architectural polychromy under the direction of Guy Habasque, and with the participation of color consultants Antoine Fasani, Jacques Fillacier, Bernard Lassus, Georges Patrix, and Erasme Saffre. The discussions of this seminar were published in 1961 in an issue of the *Cahiers* of this Center [21].

After the modern movement (represented mainly by Le Corbusier, Frank Lloyd Wright, Mies van der Rohe, and Walter Gropius), the postmodernist reaction of the 1970s and 1980s was accompanied by a different view about color and polychromatic compositions. Postmodernism brought about a host of architects concerned with the references to history and the environment, and polychromy in architecture also acquired a new meaning under these orientations. As examples, the works by Charles Moore, Robert Venturi, Michael Graves, and Stanley Tigerman (in the USA), Paolo Portoghesi and Aldo Rossi (in Italy), Aldo van Eyck (in the Netherlands), and Mario Botta (in Switzerland) can be mentioned. In Latin America, there have been also outstanding cases of recognized masters of architecture who are paradigmatic for their conception and application of polychromy. Three of them deserve a special mention: Carlos Raúl Villanueva in Venezuela, Luis Barragán in Mexico, and Clorindo Testa in Argentina [5].

Definition

There are two kinds of primary colors that are often confused or conflated. They can be called “physical primaries” and “visual primaries.” Sets of three “physical primaries” in the form of lights, paints, or inks can be mixed to produce a comprehensive range of other colors. These sets are “primary” because they have been found to deliver the most extensive and useful range of other colors. Colors are also recognized as “primary” by virtue of their appearance. These are the “visual primaries.”

Introduction

Much of the confusion that surrounds the topic of color can be exposed in a discussion about primary colors. Primary colors, for some people, are just colors that are particularly vivid. For those who work with color, there are two kinds of primary colors that are often confused or conflated. They can be called “physical primaries” and “visual primaries.”

Sets of three “physical primaries” in the form of lights, paints, or inks can be mixed to produce a

comprehensive range of other colors. These sets are “primary” because they have been found to deliver the most extensive and useful range of other colors. The particular lights or paints that work best can be recognized by their appearance: for lights, they appear orange-red, yellow-green, and violet-blue, but they are usually identified simply as red, green, and blue. The mixing process for lights is additive. For paints and inks, the mixing process is subtractive. Best results are obtained with paints or inks that appear purplish red, slightly greenish blue, and yellow. These are best identified as magenta, cyan, and yellow, but they are often loosely identified as red, blue, and yellow. The reds and blues for additive mixing appear different from those for subtractive mixing, but confusion can arise because of the range of different “reds” and “blues,” where an orangish red and a purplish red are both “red.”

Colors are also recognized as “primary” by virtue of their appearance. These are the “visual primaries.” In the continuous circle of hues, there are four that are recognized as “unique”: a yellow that appears neither greenish nor reddish, a red that appears neither yellowish nor bluish, a blue that appears neither reddish nor greenish, and a green that appears neither bluish nor yellowish. These visual primaries serve as conceptual reference points and, together with white and black, anchor the Natural Color System (NCS), which orders colors according to how they appear. Confusion can arise when visual primaries are thought of as the same thing as physical primaries. Confusion can be overcome when the distinction is maintained between visual appearances, on the one hand, and the lights, paints, and inks which give rise to those appearances, on the other hand.

Before going deeper into the two main questions – what are the primary colors and what makes them “primary” – it will be helpful to consider the nature of color itself.

The Nature of Color

Color means different things to different people. There are the colors that physicists measure, the colors that chemists analyze, the colors that

psychologists study, the colors that artists brush onto paper or canvas, and the colors that people talk about in general conversation. All these may be related, but they are not the same kind of thing.

It is possible to identify seven different “kinds of color” [1], but for present purposes, a broad distinction can be made between the physical aspects of color and color as it is experienced in perception. In general conversation, a rose or the setting sun might be described as red, and for most people that red would be a physical property of the rose or the sunlight. They might also recognize as red the subjective visual experience they have when they look at the rose or the setting sun. The one word “red” is used for two different kinds of thing. The lack of distinction between the physical and visual aspects of color is responsible for much of the confusion that exists in connection with color in general and with primary colors in particular.

Confusion Between the Physical and Visual Aspects of Color

The confusion is evident in what might be assumed to be an authoritative definition. In the *Concise Oxford Dictionary* [2], a primary color is defined as “any of the colours red, green, and blue, or (for pigments) red, blue, and yellow, from which all other colours can be obtained by mixing.” In this definition, the meaning of the word “color” changes halfway through. Pigments are physical substances. A particular pigment might appear red, but that redness is not the same thing as the pigment itself. It can help to remove the confusion if physical and visual are added after the word “color” to clarify the distinction between color meaning something physical, on the one hand, and color meaning visual experience, on the other hand. Then that definition could be reworded as follows: “any of the colors (physical) . . . from which all other colors (visual) can be obtained by mixing.”

The same change of meaning can be recognized in another definition, this from *The Color Compendium* [3]: “Simply stated, primary colors are ones that cannot be mixed or formed by any

combination of other colors.” This could also be reworded as follows: “. . . primary colors (visual) are ones that cannot be mixed or formed from any combination of other colors (physical).”

Evolution of Ideas About Primary Colors

Although the definitions above treat the physical and the visual aspects of color as if they were the same thing, they do illustrate the two main ideas about what should be understood by primary colors. One is that primary colors are physical and are used in mixing processes; the other is that primary colors are visual and serve as perceptual and cognitive reference points. The evolution of these ideas can be traced through history.

Greek Philosophers

In the fifth century BC, Empedocles recognized four principal colors as corresponding with the four elements: black, white, red, and green with earth, air, fire, and water [4, p. 15]. For Aristotle, white and black, combined in different proportions, were the sources of other colors. In a line between white and black, he identified five other principal colors – yellow, red, violet, green, and blue. “. . . from these all others are derived by mixture.” [5, p. 698].

Leonardo da Vinci

Closer to the present time, but with echoes of Empedocles, Leonardo da Vinci wrote that

white is the first among the simple colors, and yellow the second, green the third of them, blue is the fourth, and red is the fifth, and black the sixth. And white is given by light, without which no color may be seen, yellow by earth, green by water, blue by air and red by fire, and black by darkness . . . [6, p. 70].

These six colors would seem to correspond with visual primaries as reference points. On the mixture of colors Leonardo wrote,

I call simple colours those which are not compounded and cannot be compounded by means of a mixture of other colours . . . After black and white come blue and yellow, then green and tan, that is to say, tawny, or if you wish to say

ochre, and then deep purple and red. These are the eight colours and there are no more in nature, and with these I begin the process of mixing, first with black and white, and then black with yellow . . . [6, p. 72]

It seems likely that these eight colors represent the pigments which Leonardo used in his paintings. His eight simple colors would correspond with physical primaries, but their number would have had more to do with the limitations of available pigments and his own approach to the practicalities of painting than any of the theories of primary colors that are more familiar today.

Robert Boyle

Something much closer to present ideas about mixing a comprehensive range of colors (visual) from a limited set of colors (physical) can be found in the writings of Robert Boyle:

. . . there are but few Simple and Primary Colours (if I may so call them) from whose Various Compositions all the rest do as it were Result. For though Painters can imitate the Hues (though not always the Splendor) of those almost Numberless differing Colours that are to be met with in the Works of Nature, and of Arte, I have not yet found, that to exhibit this strange Variety they need employ any more than *White*, and *Black*, and *Red*, and *Blew*, and *Yellow*; these *five*, Variously *Compounded*, and (if I may so speak) *Decomposed*, being sufficient to exhibit a Variety and Number of Colours, such, as those that are altogether Strangers to the Painters Pallets, can hardly imagine. [7, pp. 219–220]

There are two significant features of this passage. First, it shows that the possibility of producing a complete sequence of hues with only three paints (physical colors) was well established. Second, it introduces, by implication, the concept of color gamut. A gamut is the range of colors (visual) that can be produced with a given set of colors (physical). Although with Boyle's *Red*, *Blew*, and *Yellow* it was possible to produce all the hues, it was not possible to produce all the colors – colors of greater “splendor” were out of reach. With *Red* and *Blew*, it was possible to produce a range of purples but not the vivid purples of some flowers. The word “hue” is often used as a synonym for “color,” but in a discussion of primary colors, it is important to recognize that

hue is just one of the dimensions of color. Boyle's "splendor" is another dimension which refers to how vivid a color may be. Words used today for this dimension include intensity and saturation as well as the more specialist terms "chroma" and "chromaticness."

Jakob Christoph Le Blon

While Boyle was a scientist, Jakob Christoph Le Blon was an artist. Le Blon developed a system of printing with transparent inks from three or four plates on white paper that is essentially the same as the process used by printers today. Three plates, one inked with yellow, one with red, and one with blue, were printed one over the other. "Painting can represent all *visible* Objects, with three Colours, *Yellow, Red, and Blue*; for all other Colours can be compos'd of these *Three*, which I shall call *Primitive*" [8]. Sometimes Le Blon used a fourth plate, inked with black, much as printers today use black to deepen the colors and sharpen the image.

Isaac Newton

Isaac Newton experimented with prisms and demonstrated that different wavelengths of light are refracted by a prism to a greater or lesser extent and that the refracted light appears in different colors. When projected onto a white surface, the refracted light is spread out to reveal the colors of the spectrum. In Newton's words, "The Light whose Rays are all alike Refrangible, I call Simple, Homogeneal and Similar . . . The Colours of Homogeneal Lights, I call Primary, Homogeneal and Simple . . ." [9, p. 4]. For Newton, therefore, a primary color was light of a single wavelength.

The spectrum can be divided and subdivided many times over, so the number of primary colors in this physical sense is very large indeed. But Newton chose to name just seven: "The original or primary colours are red, yellow, green, blue and a violet-purple together with orange, indigo and an indefinite variety of intermediate gradations" (Newton, quoted in [10, p. 225]). Newton developed a circular diagram, divided into seven segments, which could be used to determine the likely appearance of a given mixture of his primary lights.

Thomas Young

The fact that it was possible to mix a comprehensive range of colors (visual) from a limited set of primary colors (physical) led George Palmer and Thomas Young, working independently, to similar insights about what there must be in the eye that enables humans to experience such a wide range of color appearances. Young's speculation has been confirmed in its essential details:

Now, as it is almost impossible to conceive each sensitive point of the retina to contain an infinite number of particles, each capable of vibrating in perfect unison with every possible undulation, it becomes necessary to suppose the number to be limited, for instance, to the three principal colors, red, yellow, and blue . . . and that each of the particles is capable of being put in motion less or more forcibly by undulations differing less or more from perfect unison . . . each sensitive filament of the nerve may consist of three portions, one for each principal color. [11, p. 147]

James Clerk Maxwell

Where Le Blon had demonstrated that an image could be reproduced in a print by the subtractive mixing of three transparent inks, James Clerk Maxwell demonstrated how an image could be reproduced by the additive mixing of colored light. The first color photograph, taken by Thomas Sutton, was used as an illustration for a lecture by Maxwell in 1861 [12, p. 321]. A ribbon had been photographed successively through a red, a green, and a blue filter. The three photographs were then projected through corresponding filters so that the three images were superimposed on the screen.

Maxwell also developed a means of measuring color. When a disk with segments in different colors is spun at high speed, the colors blend and a new color is seen. Three paper disks, one in each of the additive primary colors (physical), are interleaved in such a way that the visible proportions of each can be adjusted. A disk in the color that is to be measured is fixed over the three interleaved disks. The superimposed disks are then spun in a series of trials, with the proportions of the three primary colored disks being adjusted after each trial, until the combination of three primary colors matches the color to be measured. The measurement is then expressed in terms of the relative

amounts of each of the primary colors needed to achieve the match. In this process, colors (physical) and colors (visual) come together. The colored papers are physical, but it requires a visual judgment to establish a match.

Ewald Hering

During the nineteenth century, the idea that color vision depends on three different kinds of sensitive cell in the eye, with three corresponding primary colors, became established. It was challenged by Ewald Hering, who used his own observations as a starting point. He concluded that there are six fundamental colors (Urfarben) that must have their counterpart in the nervous system associated with vision. Hering's Urfarben can be called primary colors (visual). The claim is that any color can be described in terms of its relative resemblance to these Urfarben which serve as reference points. They are the basis of the Swedish standard Natural Color System [13]. After black and white, Hering defines what are now recognized as the "unique hues":

... there are four outstanding loci in the series of hues that make up the closed circle: first the locus of the yellow that shows no remaining trace of redness, and yet reveals no trace of green; second the locus of the blue for which the same is true. These two hues may be called *primary yellow* and *primary blue* (Urgelb and Urrblau). Likewise we can name, third, the red, and, fourth, the green that are neither bluish nor yellowish primary red and primary green (Urrot and Urrgrün). [14, p. 42]

The CIE System

In 1931, the International Commission on Illumination (CIE) established the system of color measurement that is today's world standard [15, pp. 59–63]. All possible colors (physical) can be plotted on the CIE chromaticity diagram. The position of a color on the diagram is determined by the relative output of three primary lights that, when mixed together, would match the color. The measurement can be expressed in terms of tristimulus values. As with Maxwell's system of spinning disks, the matches that underpin the CIE system were initially the result of visual judgments made by human observers. But there is no set of three colored lights (physical) that can

match all possible colors (visual). The most vivid colors (visual) are those of Newton's homogeneous lights – the pure colors of the spectrum. In order to measure such colors, it was necessary to reduce their "splendor" by introducing negative values. This led to complexities that were overcome by clever mathematics and the introduction of theoretical "super light sources" that could not be physically realized but that were able to deliver matches for the spectral colors.

Primary Colors in the Twenty-First Century

The different ways in which the term "primary colors" is used today can be related to these ideas that evolved in the past.

Further Problems with Standard Definitions

The definitions of primary colors, quoted in the section "[Confusion Between the Physical and Visual Aspects of Color](#)" above, not only confuse the physical and visual aspects of color, but they are also misleading in other ways. As Boyle observed, and the CIE confirmed, there is no set of primary colors (physical) from which all other colors can be obtained by mixing. It is possible to obtain all the hues but not all the colors – only those within a limited gamut. The CIE had to resort to its theoretical super lights. A full gamut of all other colors, right out to Newton's homogeneous lights, can only be achieved in theory, with the CIE super lights, and not in practice.

The second definition, that primary colors cannot be mixed from a combination of other colors, is also misleading. It would be true of the CIE theoretical super lights but not in the case of normal lights, paints, or inks. It would make no sense to claim that primary colors (physical) cannot be mixed from a combination of other colors (physical). The primary colors that do make sense in the context of this definition are visual colors. Leaving aside black and white, the visual primaries should be the unique hues – Hering's *Urfarben* – and there is nothing unmixable about these. A paint that appears yellow can be mixed with paint that appears magenta to produce a red

that is neither bluish nor yellowish and with a paint that appears blue to produce a green that is neither bluish nor yellowish.

Primaries for Mixing Other Colors in Print and on Screen

Primary colors (physical) for mixing a large range of other colors (visual) have particular application for the reproduction of colored images in print and on the television or computer screen. There is scope for further confusion here because the mixing processes are not the same. When layers of transparent ink are superimposed in a print, the result is a subtractive mixture. Additive mixture occurs when pools of colored light are projected to overlap or when the small points of colored light blend on a screen.

It was not until the nineteenth century that the difference between subtractive and additive processes was recognized. Then it became clear that the primaries (physical) for each process were not only different in that pigments and dyes are physically different from colored lights but also that the most useful sets of three colors (physical) appear different. The two sets are listed in the first definition set out in the section “[Confusion Between the Physical and Visual Aspects of Color](#).” Additive primaries are listed first, then the subtractive primaries. They are described as red, green, and blue or (for pigments) red, blue, and yellow. This suggests that the only difference between the two sets is that one set has green and the other set has yellow. However, the lights that work best for additive mixture appear orange-red, yellow-green, and violet-blue, while the inks for subtractive mixture appear purplish red (magenta), slightly greenish blue (cyan), and yellow. The differences between the orange-red and magenta, and between the violet-blue and cyan, are masked by the way the names “red” and “blue” stretch to cover a range of different hues. What makes these two sets primary is that they have been found to deliver the most useful gamuts of other colors (visual). The gamuts could be increased for each process by adding further inks or lights, but any slight improvement would not justify the very large extra costs that this would involve.

Mixing with a Larger Number of Colors (Physical)

When a color is required in a print that is beyond the reach of the cyan, magenta, and yellow process inks, it may be achievable with a mixture of inks formulated according to the Pantone Matching System[®]. This system has 14 separate inks that can be premixed before being used on the press.

A similar number of different colors (physical) are used to mix the very large range of different colors (visual) that are available for painting the interior and exterior of buildings. The tinting machines for Dulux Australia have four main bases and 13 different tints that add pigments to a base according to given formulas.

Today’s artists, like Leonardo before them, need not restrict themselves to a set of three primary colors (physical). They use as many different paints as they need to achieve the results they want.

Primary Confusion

The confusion surrounding the different notions of primary colors, especially that between primary colors (physical) and primary colors (visual), was the subject of a paper that Green-Armytage gave at a conference on color education [16]. This confusion is especially evident in what he calls traditional art school color theory.

Among the most widely used and influential books on color theory for artists are *The Art of Color* [17] and the condensed version *The Elements of Color* by Johannes Itten [18]. Itten’s account should be read carefully [17, p. 34, 18, p. 29]:

... let us develop the 12-hue color circle from the primaries – yellow, red and blue. As we know, a person with normal vision can identify a red that is neither bluish, nor yellowish; a yellow that is neither greenish nor reddish; and a blue that is neither greenish, nor reddish.

These definitions are reminiscent of Hering’s definitions except that green is not included as a primary. However, green is included in the definitions of primary yellow and primary blue. Itten did not (could not?) describe primary blue as

neither reddish nor *yellowish* or primary yellow as neither reddish nor *bluish*.

Itten goes on to describe secondary colors as "... three mixed colors, each composed of two primaries." Later in the books [17, p. 136, 18, p. 88], he describes green as "... the intermediate between yellow and blue. According as green contains more yellow or more blue, the character of its expression changes." Did he mean that there could be more or less yellow or blue paint in the mixture which resulted in the perception of green? Or did he mean that in the green percept there might be more or less resemblance to yellow and blue as primary colors (visual)?

It is not clear from the books whether Itten associated his primary yellow, red, and blue with any particular pigments. There is certainly no claim that with three such paints all other colors can be obtained by mixing. But what is clear from experiment is that three paints which might fit Itten's definitions would not work so well for producing a comprehensive range of other colors (visual) as would paints that look the same or similar to the cyan, magenta, and yellow process inks used by printers. Itten's primaries would not be a good choice as primary colors (physical).

And without green they are not satisfactory as primary colors (visual).

Plotting the Gamut for a Given Set of Colors (Physical)

The color circle of the Natural Color System (NCS) can be used as a diagram on which the appearance of paints can be plotted. The unique hues, as reference points, are spaced at equal intervals round the circle. The achromatic colors – the pure whites, grays, and blacks – are located in the center of the circle. The most vivid colors (visual) that can be imagined are located on the circumference. The less vivid colors (visual) are located between the circumference and the center, closer to the circumference or to the center as they are more or less vivid. Points on the diagram representing two paints can be connected by mixture lines to indicate the changing appearance of the mixtures as they contain more or less of each paint. The mixture lines connecting three paints trace an irregular triangle and mark the gamut of appearances that can be achieved with that set of paints. This makes it possible to compare the relative merits of different sets of primary colors (physical). The gamuts achievable with different sets of "primaries" are illustrated in Fig. 1.

Primary Colors, Fig. 1 Mixture lines connecting two sets of "primary" paints plotted on the *color circle* of the Natural Color System (NCS)

Primary Colors, Fig. 2 Four sets of primary colors identified loosely as “red,” “yellow,” “green,” and “blue” to show how use of color names contributes to the way the sets are confused

On the left, cadmium yellow pale, cadmium red, and ultramarine are typical of the paints regarded as “primary” in traditional art school color theory. While these paints can deliver all the hues, the greens and purples are very dull. If more vivid greens and purples are required, an artist would need to include more paints on the palette. A more extensive gamut can be achieved with the addition of a turquoise or cerulean blue and a vivid magenta such as Bengal rose. The paints used on the right were lemon yellow, Bengal rose, and turquoise blue. These paints appear similar to the yellow, magenta, and cyan process inks as used in printing. Their status as preferred primaries for subtractive mixing is clear from the more extensive color gamut that they can deliver. Within the mixture lines are the colors (visual) that could be achieved with that set of paints. If a desired color (visual) would be located outside the mixture lines, there may be a paint that could be added that would bring that color (visual) within reach [19].

The Role of Color Names in the Confusion of Different Kinds of Primaries

In the section “[Primaries for Mixing Other Colors in Print and on Screen](#)” above, it is argued that the difference between primaries for additive and subtractive mixing is masked by the way that the names “red” and “blue” are each used to describe

a range of different hues. The only point of difference between the two sets of primaries seems to be that green is a primary for additive mixing and yellow for subtractive mixing; both sets include “red” and “blue.” It might seem that the unique hues, as visual primaries, resolve the conflict by including both yellow and green, but this only adds to the confusion. And further confusion comes from the common expectation of art students that they can “mix all the other colors” from the primaries red, yellow, and blue. The red, yellow, and blue of traditional art school color theory are typically defined in terms used for the visual primaries, the unique hues. The four sets of primaries are compared in Fig. 2.

Conclusion

There has been a long history of singling out particular colors as being somehow special. The realization that a comprehensive range of colors (visual) can be mixed from a limited set of paints, inks, dyes, or lights led to the development of ways to reproduce fully colored images in prints and projected photographs, techniques pioneered by Le Blon and Maxwell. This realization also inspired ideas about the physiology of the eye and how it is that humans can experience such a great variety of colors.

Concepts of primary colors can help people to work successfully with colors. These concepts can also be confused. The key is to recognize that there are two kinds of primary colors: physical primaries, which take the form of lights, paints, inks, and dyes to be used in mixing a comprehensive range of other colors (visual), and visual primaries as very specific visual experiences – pure white, black, and the four unique hues. By using the visual primaries for reference, the physical processes involved in the production and reproduction of colors, which may involve the physical primaries, can be monitored and controlled.

Protanopia

Galina V. Paramei¹ and David L. Bimler²

¹Department of Psychology, Liverpool Hope University, Liverpool, UK

²School of Psychology, Massey University, Palmerston North, New Zealand

Synonyms

Color blindness; Congenital color vision abnormality; Daltonism; Dichromacy; “Red-blindness”; Red-green deficiency; X-linked inherited color vision deficiency

Definition

Protanopia (from the Greek *protos*: first + *an*: not + *opia*: a visual condition) is a congenital form of severe color deficiency (dichromacy) affecting the red-green opponent color system. Protanopes do not distinguish between colors along a specific direction (protanopic confusion lines) in color space and are able to match all colors using two primaries (unlike trichromats who require three primaries). Protanopia is linked to the X-chromosome and arises from loss or alteration of the gene encoding the opsin of the long-wavelength (L-) photopigment; this malstructure results in the absence of functioning L-cones in the retina. Protanopia follows a recessive pedigree pattern, with incidence of ca. 1% in the Caucasian male population. It is distinct from protanomaly in which some degree of discrimination among such colors remains.

Protanopia, Fig. 1 Adaptive optics retinal imaging: Pseudocolor image of the protanopic cone mosaic; all cones are of the M- (“green”) or S- (“blue”) type. (Source: Carroll et al. [2]; Fig. 4b, p. 8465. Copyright (2004) National Academy of Sciences, USA)

Retinal Mosaic

At the level of retinal function, protanopia is the absence of L-cones (Fig. 1) (► [Cone Fundamentals](#); ► [CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams](#)), i.e., cone cells expressing a photopigment containing an L-opsin component, tuned for selective sensitivity to longer wavelengths such as orange and red light [1].

Genetic Background

Functional loss of the L-cone photoreceptor cells is caused by a mutant cone photopigment gene on the X-chromosome (► [Genetics of Photoreceptors, Genetics and Color Vision Deficiencies, Genes of Cone Photopigments, Genes and Cones](#)). The gene coding for the L-opsin may be missing altogether from a protanope’s genome; it may be replaced by a second copy of the M-opsin (sensitive to slightly shorter wavelengths), or it may be present but damaged so that the protein is not expressed or cannot be transported to the ciliary segment of cone cells expressing that gene [2–4].

When present, the L-opsin gene is located on the X-chromosome, followed by one or more copies of the M-opsin gene (► [Genetics and Color Vision Deficiencies, Genes of Cone Photopigments, Genes and Cones](#)). This architecture, and the high similarity of the two genes, facilitates mismatching of DNA during meiotic crossover, leading to deleterious mutations of the L-opsin encoding gene [3, 4].

With two X-chromosomes, females are far less prone to protanopia. Notably, mothers and daughters of protanopes can be heterozygous for protanopia (i.e., carriers of the condition) with one normal and one aberrant X-chromosome; the former is active in a portion of their cone cells, providing enough L-cones to sustain normal trichromacy. However, minor departures from normality are discernible [5], including reduced sensitivity to long wavelengths, known as Schmidt's sign, and reduced subjective prominence of red-green dissimilarity [6].

Confusion Lines

L-signal/M-signal comparison in bipolar ganglion color-comparison cells is not present in protanopes (Color Vision, Opponent Theory); hence there is no difference in appearance of any colors which differ only in the L–M signal. That is, although protanopes lack the L- or “red” cones, they are not “red blind” in a literal sense but rather are red-green blind. Examples of colors confused by protanopes are red, yellow and green or cyan, gray, and purple. Plotted in a chromaticity diagram (► [CIE Chromaticity Diagrams, CIE Purity, CIE Dominant Wavelength; ► CIE Chromaticity Coordinates \(xyY\)](#)), the confused colors lie on straight “confusion lines” that converge at the protanope copunctal point (Fig. 2).

Luminous Efficiency, Luminance Effect, and Wavelength Discrimination

In the absence of L-cones tuned to longer wavelengths, protanopes display a distinctive insensitivity to 550–750 nm lights (orange and red)

Protanopia, Fig. 2 Confusion lines indicate colors that cannot be distinguished by a protanope. The line going through the white point (*W*) indicates neutral (achromatic) colors. The lines converge at the copunctal point defining the chromaticity of the missing L-cone fundamental. Drawn in the CIE 1931 chromaticity diagram [7]

[8]. Their luminosity function has peak sensitivity around 540 nm compared to the maximum near 555 nm of normal trichromats, i.e., it is blue-shifted toward the $\lambda_{\max}$ of the M-cone pigment [1, 9]. Phenomenally, reds appear relatively dark for protanopes and are confused with grays and bluish turquoise.

Thus, protanopes attend more to luminance changes than normal trichromats as a color cue, compensating for their poor hue discrimination [10]. Notably, at lower photopic and mesopic luminance levels, protanopes' color discrimination slightly improves, perhaps reflecting input from rod cells [11].

Hue discrimination, as a function of wavelength, is considerably worse in protanopes than in normal trichromats. Their lowest discrimination thresholds ($\Delta\lambda$), approaching the trichromatic value, are around the protanopic “neutral point,” ca. 490 nm (see below). $\Delta\lambda$ rises on both sides of this minimum, increasing rapidly on the short-wavelength side and on the long-wavelength side until wavelengths are not distinguished beyond approximately 550 nm [8].

Color Perception

A protanope recognizes far fewer distinct colors than a trichromat (► [Color Categorization and Naming in Inherited Color Vision Deficiencies](#)). Instead of all possible equiluminant colors being arranged in a two-dimensional plane (► [Psychological Color Space and Color Terms](#)), for a protanope they form a single-dimensional line, running between the two extremes of saturated blue and saturated yellow, separated by a “neutral zone” of subjective gray, with midpoint at ca. 490 nm of spectral light (blue-green for normal trichromats) [12]. Protanopes distinguish approximately 21 steps along this one-dimensional line, each corresponding to a separate band of interchangeable colors [1]. The usually separate chromatic qualities of “saturation” and “hue” are thus combined along this line. This protanopic linear representation of equiluminant colors is part of a broader reduction of a three-dimensional into a two-dimensional color space.

Whether the subjective qualities of the two extremes are identical to the normal trichromatic “blue” and “yellow” remains controversial and rests on reports from a handful of individuals with unilateral dichromacy. The blue-yellow convention is used in dichromacy simulation software, which converts color scenes to show how a protanope would see them [13].

Despite this model of a two-hue palette for self-luminous colors, the color percepts of protanopes remain in question. Their object-color palette was proved to include all six Hering component colors (red, green, blue, yellow, white, and black) [14]. However, in contrast to normal trichromats, protanopes perceive only a weak green component in object-colors and do not experience “unique green,” while their red and green components are confounded with an achromatic element (► [Color Categorization and Naming in Inherited Color Vision Deficiencies](#)).

Diagnosis of Protanopia

A number of tests for protanopia are available, varying in sensitivity, selectivity, and ease of use

[15, 16] (► [Color Vision Testing](#)). Pseudoisochromatic plates and arrangement/panel tests, widely used in survey/field studies, directly address a protanope’s confusions between color pairs along the confusion axis.

In the pseudoisochromatic tests (Ishihara plates, Hardy-Rand-Rittler test), each diagnostic plate shows a normal observer design (► [Pseudoisochromatic Plates](#); ► [Color Vision Testing](#)) – one- or two-digit numbers or curved lines defined by a color difference – which disappears for protanopes, so that the design vanishes or is supplanted by an alternative design, demarcated by a different chromatic distinction.

In the arrangement tests (► [Color Vision Testing](#)) (Farnsworth-Munsell 100 Hue test, Farnsworth D-15 test), the one-dimensionality of a protanope’s color “plane” collapses into a line (► [Color Circle](#)), causing drastic departures from a normal observer’s sequence. Errors, or cap transpositions “distances,” are summed to quantify the severity of protanopia. Plotted graphically, the transpositions in the D-15 manifest as diametrical circle crossings, indicating the protanopic angle of the confusion axis (► [Color Perception and Environmentally Based Impairments](#)).

The “gold standard” of diagnosis of protanopia is the Rayleigh match on a small viewing field (2°) of the Nagel anomaloscope (► [Color Vision Testing](#)) [16]. Unlike normal trichromats who reproducibly choose a unique ratio of red and green to match the yellow intensity, a protanope can match *any* red/green ratio to the yellow light by adjusting the luminance of the latter and dimming it if the mixed light is mainly red, while a green-dominated mixture requires for a protanope a more luminant yellow. Notably, some protanopes, when setting Rayleigh matches tested with a large viewing field (10°), perform as anomalous trichromats. Various factors related to retinal eccentricity are presumed, e.g., rod intrusion, S-cone intrusion, spatial variation in the macular pigment, etc. [1].

More recently developed computerized tests for color vision diagnosis, the Cambridge Colour Test [17] and the Colour Assessment and Diagnosis test [18] (► [Color Vision Testing](#)), interactively quantify any loss of chromatic sensitivity

along the protanopic confusion line. For a protanope, in the frame of the CIE ($u'v'$) 1976 chromaticity diagram (► [CIE \$u'\$, \$v'\$ Uniform Chromaticity Scale Diagram and CIELUV Color Space](#)), a MacAdam ellipse of indistinguishable colors displays a major axis lengthened to infinity and orientation pointing to the protanope copunctal point [17].

Incidence of Protanopia

The prevalence of inherited protanopia varies between human populations [19]. For Caucasian populations, the reported incidence of protanopia is 1.01% in males and 0.002% in females [1]. Recent surveys of red-green deficiency in populations of different racial origin found the incidence of protanopia in Caucasian males to vary between 0.96% and 1.27%. In a marked difference, the incidence is about half this rate in indigenous populations in Asia, Africa, Australia, and Central America but is observed to rise in geographic areas that have been settled by incoming migrants, in particular in coastal areas visited by Europeans in historical times [19]. The increasing prevalence of congenital red-green deficiencies, including protanopia, has tentatively been explained by a relaxation in selection pressures as hunting and gathering cultures evolve toward industrialized societies [1]. More recently, however, it is rather attributed to genetic drift and founder events (variable sampling of the gene pool contingent on the population size) [19].

Pseudoisochromatic Plates

Marisa Rodriguez-Carmona
Optometry and Visual Science, City University

Synonyms

Color vision test; Isochromatic color confusions; Screening plates

Definition

Printed pseudoisochromatic plates are the most widely used type of color vision test to screen for color vision deficiency. The principle is that the color of a target (digit or letter) embedded in a background of another color appears “falsely of the same color” to color-deficient people. Target and background chromacities are chosen carefully to be the ones confused by people with color vision deficiency.

Design of Pseudoisochromatic Plates

Pseudoisochromatic plates must be carefully designed in order to be effective. As a result of the printing process, minor misalignments between a figure of one chromaticity and the uniform background of another undistinguishable chromaticity may reveal the shape of the digits or letters. In addition, the relative luminous efficiency of the eye varies considerably within normal trichromats and even more so in color-deficient observers. Hence, a figure and background that are equally light for one color defective are not necessarily so for another. The first pseudoisochromatic plates, introduced in Germany by Stilling in 1877, addressed these issues by breaking up the test target and background into a number of discrete patches each with its own shape and contour, and the luminance of the individual patches was varied randomly rather than being equated. This ensured (as much as possible) that neither edge artifacts nor luminance differences could be used to discriminate the target from the background; thus, the target can be detected only by color discrimination.

Stilling's pseudoisochromatic plates are all of “vanishing” design, so called because the target is read correctly by the normal trichromatic observer and not seen by the color defective (i.e., the “vanishing” figure is pseudoisochromatic to the color defective). A later variant was the “transformation” plate, where two figures are embedded in the background, one that is read by the normal observer and another that has the appropriate chromatic and lightness contrast to be read by the color-deficient observer. The Japanese ophthalmologist Ishihara published in 1917 the first edition of a set of plates that included vanishing and transformation plates, as well as hidden plates, in which the color defective can see a digit that is camouflaged for the normal by random color variation. Another design is the diagnostic or classification plate which is a more sophisticated version of the vanishing design plate that allows for differentiating between the type of red-green color deficiency, i.e., protan or deutan. The Ishihara plates are not designed for examining yellow-blue deficiencies, i.e., tritan

deficiency. In 1954, the AO-HRR (American Optical – Hardy, Rand, and Rittler) plates were printed and comprise both screening and diagnostic plates for tritan defects, as well as diagnostic and grading plates for protan and deutan defects. The plates have vanishing designs containing geometric shapes (circle, cross, and triangle) that are printed in neutral colors on a background matrix of gray dots. The saturation of the neutral colors increases in successive plates to produce designs with progressively larger color difference steps identifying different levels of deficiency.

The Ishihara and the AO-HRR pseudoisochromatic plates are often used together because their functions are complementary. The Ishihara plates are used for screening for red-green color deficiency and the AO-HRR plates to confirm protan/deutan classification, estimate the severity of red-green deficiency, and identify tritans.

Some pseudoisochromatic tests have designs containing shapes or “pathways” for the examination of nonverbal subjects and young children.

Administration of Pseudoisochromatic Plates

The majority of pseudoisochromatic tests have been designed to be viewed at 60–70 cms and standardized for natural daylight illumination (or for CIE standard illuminant C). The examiner turns the pages and controls the viewing time. An introductory plate is often included to demonstrate the visual task.

Examples of Pseudoisochromatic Plates

A number of other pseudoisochromatic tests have been produced, but none have been used as widely as the Ishihara and the AO-HRR plates. Tests have been published in Japan, e.g., the Ohkuma plates (1973), Tokyo Medical College test (1957), and Standard Pseudoisochromatic Plates (1st and 2nd editions) and in the USA, e.g., the Dvorine plates; in Germany, e.g., the Velhagen-Broschmann plates (29th edition published in 1992); in

Sweden, e.g., the Bostrom-Kugelberg plates (1972); and in France, e.g., the Lanthony Tritan Album, among many others. Despite many contenders, the pseudoisochromatic plates of Ishihara remain today the dominant instrument for routine screening of color vision.

Psychological Color Effects

Definition

Psychological color effects are the outcome of color sensations as determined by human perception and emotion, including color influences on feelings, thinking, and behavior.

Introduction and Classification

Colors may alter people's percepts and may affect how they feel. Colors with their psychological effects are most studied under three main areas: advancing and receding/retreating colors, in relation to temperature (warm vs. cool) and in relation to emotions. Advancing and receding/retreating

colors are related with visual perception where people tend to see some colors as if they are closer than they actually are or vice versa. The effect of color on warmth perception is related with feeling warm, which could be a physical or sensorial effect. In this case, some colors may increase or decrease the feeling of warmth, although the actual physical temperature remains the same. In relation to emotion, people's emotions may alter when they are exposed to different colors. There may be even more ways that colors may effect percepts and emotions, but the most studied three topics will be expanded in this overview.

Advancing and Receding/Retreating Colors

Colors in Isolation

In studies treating colors in isolation, Luckiesh provided one of the earliest arguments on the "retiring" and "advancing" effects of color letters placed in the same plane [1]. In 1918, he used an apparatus with red and blue filters "of fairly high purity" with which he altered the color of the letters *X* and *E* viewed inside wooden boxes. The subjects moved the red *X* until it appeared to lie in the same plane as the blue *E*. He found a lot of inter-subject variability, but still in most of the cases it was necessary to move the red *X* further away in order to make it appear to be in the same plane with the blue *E* [1, also cited in 2]. One explanation on the advancing quality of red comes from the operational mechanism of the eye. The lens of the eye has to adjust to focus the red light wavelengths, as their natural focal point lies behind the retina. Thus, red advances, creating the illusion that red objects are closer than they actually are [3]. This phenomenon is about the monocular depth perception of the eye where shortwave light refracts in the eye's optical media more than longwave light; thus, the equidistant sources of different colors cannot be simultaneously focused on the retina, which is also called chromatic aberration [4].

Successive studies on the advancing property of color found instances when blue was judged to be "nearer" than red. Pillsbury and Schaefer, in

1937, had subjects view either red neon or blue neon and argon lights [5]. When the lights were placed equidistantly, the blue light was judged the nearer. The explanation for this "conflict" in apparent nearness of red vs. blue is explained by subsequent research that suggests lightness (or brightness) to be the controlling quantity for apparent distance [2]. The Purkinje shift, a well-known physiological phenomenon, demonstrates that blue light appears lighter than red at low luminance levels.

Colors in Combination

In studies with color combinations, the relationship between perceived colors, e.g., contrast, becomes important. Mount et al. conducted the first outdoor research of color distance in 1956 [6]. They mounted four chromatic (yellow, green, red, blue) and four gray papers on plywood. The plywood with chromatic colors and grays attached on it was viewed outdoors against a dirt bank under full sun. Participants compared a chromatic color or a gray against a dark or light gray standard on each trial. It was found that each chromatic color was judged to be closer than its nearest matching gray. Each of the hues and the grays appeared closer when viewed against a dark standard rather than the light one. They found no difference in advancement for one hue over another. On the other hand, as saturation of a color was increased with respect to its background, its apparent position advanced (an effect equal at most to 1.5% of the standard distance). Colors having high lightness contrast with their background appeared advancing (an effect equal at most 3% of the standard distance). Thus, increasing relative contrast by increasing an object's lightness and/or saturation as compared to its background makes the object appear closer [2].

These findings are supported by the 1960 study of Oyama and Nanri [7]. They had participants compare standard and variable circular shapes in all combinations of achromatic and chromatic relations on varying backgrounds under laboratory conditions. They found that the apparent size of the figure increased as its lightness increased, while the lightness of the background decreased.

They found no effect of hue on apparent size [2, 7].

Egusa confirmed the findings of the studies above [8]. In 1983 he found an effect of hue when hemifields of different hues were compared for perceived depth. The green-blue difference in perceived depth was smaller than the red-green difference, with red appearing nearer. He also noted that a higher saturated color was judged nearer when it was red or green, but there was no such effect for the blue [8].

In the studies above, it appears that there may be a combined effect of all attributes of color, hue, saturation, and lightness, on advancing or receding/retreating colors, especially when they are viewed in combination. Lightness seems to be the most dominant attribute. Colors having high lightness contrast with their backgrounds appear advancing. Saturation seems to be the second most important attribute of color in judgments of nearness. As saturation of a color increases with respect to its background, it seems closer in the visual field [2].

In Relation to Temperature (Warm/Cool)

The definition of warm is directly associated with color as “having the color or tone of something that imparts heat, specifically of a hue in the range yellow through orange to red” [9]. Warmth perception is a multisensory experience of the immediate environment including physical (e.g., thermal properties, surface properties, etc.) and sensory (e.g., visual, tactile, olfactory, etc.) aspects.

Color in Relation to Physical Aspects (Perceived Temperature) of Warmth

Hue affects warmth perception independent from saturation and lightness [10, 11]. Although no relationship was found between colored illumination and perceived temperature [12], the following studies establish a relationship between applied hue (as in wall finishing colors) and perceived temperature. Itten’s study reports that in a blue-green room, participants felt cold at 15 °C, whereas they felt cold at 11.1 °C in a red-orange room [13]. In 1976 Porter and Mikellides found

that occupants preferred 2.2° higher indoor environment temperature in a blue room than in a red room. Occupants felt cold at 22.2 °C in a blue room, while this temperature was preferable in a red room. In a red room, they felt warm at 24 °C [14].

Color in Relation to Sensory Aspects of Warmth (Warm Colors Versus Cool Colors)

Warm colors are perceived warmer than cool colors [11, 15]. In interiors, one study reports that red and yellow induce the perception of warmth, while white is regarded as the coolest color [16]. In applied surface colors, hue influences warmth perception, where warm colors (red, orange, yellow) are regarded as being warmer than cool colors (green, blue, purple).

In a study on “nasal thermal sensation,” participants felt cold in their nasal nostril when smelling green-colored water and felt warm in their nasal nostril while smelling red-colored water. Thus, the visual sense affects the warmth perception of the olfactory sense as well [17].

Color Emotion

Color as an effective design tool influences people’s emotions in interior spaces. Red is one of the powerful colors and creates the highest number of emotional responses [18]. It is associated with surprise, happiness and sadness [19], energy, vitality and power [20], fear, and anger [21]. Thus, red evokes emotions in a range from the negative (anger, fear, and sadness) to positive (happiness, energy, power) ones [22].

Green is associated with nature and trees, which creates a feeling of comfort with a number of positive emotions such as feelings of relaxation, happiness, comfort, peace, and hope [23].

Blue is connoted with infinity and serenity in relation to the sky and the sea, representing peacefulness and relaxation [24]. Blue was found also to be associated with happiness [19], calmness, peacefulness, relaxation, modernism, coldness and dullness [25], and sadness [26].

Users usually desire colors in order to feel something or in order to create a psychological bond with an object or a space. It should also be

noted that if people indicate any color as being their least favorite in their daily lives, in some instances they also associate an interior with that specific color with disgust [22].

Psychosomatic Effects of Color

Each color and color combination has its own sensation. Individually or in relation to each other, colors may become eye irritants or may cause headaches. They can effect brain waves, hearth rates, blood pressure, and respiratory rates [27]. There is an ancient and widespread faith in the healing power of color, some of which is studied under color healing or color therapy [28, 29].

Psychological Color Space and Color Terms

David L. Bimler

School of Psychology, Massey University,
Palmerston North, New Zealand

Synonyms

Color appearance solid; Color similarity space;
Relational color space

Definition

Psychological color space is the relational structure among color stimuli that can be found using empirical tasks that assess color similarities. Color terms are the lexical categories (which can vary across different ethnolinguistic groups) that are used to label, or describe, color appearances organized as meaningful partitions of the psychological color space.

Psychological Color Space

A color-ordering system requires three independent modes of variation to accommodate the full gamut of color experience and arrange all possible hues within a coherent continuum, in which similar pairs of colors are adjacent neighbors. This requirement, so familiar now, only emerged after a long history of trials with one- or two-dimensional schemes [1]. Here colors are considered in isolation as opposed to in the context of other colors where induced simultaneous contrast effects complicate color appearance.

“Psychological color space” is synonymous with a “color solid” containing all physically attainable hues. Numerous psychological qualities or attributes have been nominated as its underlying dimensions ([1], Chap. 5). The long delay before the acceptance of the three-dimensionality of color space suggests that most of these attributes are not immediately evident and require a

trained observer. Perhaps the most intuitive of these qualities, the circular sequence of hues around a color wheel, only became an organizing principle after Newton’s description of the prismatic spectrum. Later theorists refined the Newtonian color wheel by inserting nonspectral purples between the red and violet spectral extremes.

One tradition portrays the color solid as a sphere or as a pair of cones or pyramids joined at their bases. The “equator” is the color wheel, containing the purest, most saturated form of each hue. A *hue angle* locates each hue within the rainbow sequence. Perpendicular to the wheel and through its center runs an achromatic axis of gray tones, connecting the polar extremes of white and black. Derived forms of a given hue share the same angular coordinate, occupying space between that point on the wheel and the axis. In effect they comprise one page in a “book of color” radiating out from a central spine. In the Natural Color System – one example of a color space – these intermediate hues are derived from the pure hue by dilution with various amounts of black or white or both.

Clearly this is a cylindrical coordinate system. As well as the angular coordinate, it implies a radial coordinate (the distance out from the axis), variously labeled as “saturation” or “colorfulness” or “purity.” The third coordinate, running parallel to the axis, is some version of “lightness.”

Hering [2] argued that in addition to lightness (defined by its extremes black and white), “red” and “green” are the extremes of a second opposition. Each cancels out the other so the two cannot coexist. “Blue” and “yellow” are a third opposition. These three oppositions form an alternative way of spanning color space, with rectilinear axes which specify a hue by its content of “redness vs. greenness” and “blueness vs. yellowness.” In terms of radial coordinates, the “cardinal hues” of yellow, red, blue, and green might be located at 0°, 90°, 180°, and 270°, respectively.

In practice the purest yellow hues are relatively light, and conversely the purest purples are relatively dark. Thus, all saturated hues can only be located on the equator of the color solid by treating the lightness scale differently on each of

the radial color “pages.” The alternative is to treat “lightness” as an *objective* property that can be measured with a photometer and slice color space into planes of equal lightness, with the most saturated example of each hue located empirically in the appropriate plane (in some depictions of color space, lightness is replaced with a “brightness” axis, a more subjective quality which also increases with saturation). The effect is to tilt the color wheel to form an oblique angle with the achromatic axis, distorting the geometry of double-cone and double-pyramid models of color space.

In addition, “maximum saturation” is not a constant quality around the wheel. The most saturated “reds,” for instance, are perceptually more intense than the most saturated blues, i.e., more dissimilar from the corresponding gray tone. Incorporating these aspects of color perception produces a less regular color solid. In the widely used “Munsell color space” [3], the radial coordinate (chroma) applies the same metric across hues, reaching its highest values for the intense red hues of intermediate lightness so that they bulge out on the side of the solid. In explanations of how color names are assigned to color space, the geometrical salience of this region marks the red hues as particularly “namable,” along with “black” and “white” [4].

Munsell space emphasizes the principle of *uniformity*, that the distance between two hues in the space should reflect the perceptual dissimilarity between them. That is, a given distance at any region of color space, such as a unit increment in saturation level, should correspond to the same inter-hue dissimilarity. This empirical approach also led Munsell to expand the blue/red quadrant of the color wheel and insert “purple” as a fifth cardinal hue, contrary to the Hering polarities.

In another application of the uniformity principle, hue samples were chosen to form a square grid spanning each equal-lightness plane [5]. That is, dissimilarities were intended to be the same between each pair of adjacent samples, as far as departures from Euclidean geometry would permit. The hue samples are also specified by their coordinates on three rectilinear axes *L* (lightness), *g*, and *y*, but the *g* and *y* scales were determined

afterward rather than fundamental to this uniform color scale scheme (the OSA-UCS). Again, the resulting color solid is irregular.

An extension of the uniformity principle takes advantage of multidimensional scaling methods (MDS) to explore color ordering. Here ratings of dissimilarity among pairs of hue samples are elicited from observers and analyzed with MDS algorithms, yielding geometrical solutions where points representing the samples are arranged so that distances among them reflect the dissimilarities. In a series of empirical studies, the samples were selected from the Munsell system to vary across all three coordinates [6]. The results generally support that system’s uniformity.

Numerous other models of color space exist, emphasizing different aspects of color experience. There is a tension between the uniformity principle and other features that might be desirable, in particular the “linearity” principle that mixtures of two colored lights should be represented by points along a straight line. CIE tristimulus space is an example of a physiological model where distances are strongly nonuniform.

Given a corpus of unconstrained labeling data, in which subjects collectively applied a pattern of color terms to each stimulus, one measure of dissimilarity between any pair of stimuli is the difference between the two patterns used to describe them [7]. These dissimilarities can be reconciled with distances in a geometrical color space by introducing a “metric,” i.e., a distance/dissimilarity function that varies with location in the space [7].

Why Three Dimensions?

In the final analysis, three dimensions are necessary – though they can be conceptualized and spanned in different ways – because human color vision rests on the existence of three distinct populations of photoreceptor cells in the retina (*S*, *M*, and *L* cones), reducing the spectral information within a given stimulus to three levels of cone outputs. In the first stage of visual processing, neurons in the retina create combinations of the raw cone outputs that are more informative than single values in isolation: a sum (*L* + *M* or “luminance”) and two cone-output differences

(L-M and S-(L + M)). These combinations provide the three axes of *cone excitation space*, widely used in vision research to define experimental stimuli and results.

However, physical light can vary along far more than 3 degrees of freedom. Thus, two stimuli with physically different light spectra may appear perceptually identical (“metamers”) and be shown as the same point in color space because they provide the same stimulation to each of the cone classes. That is, trichromatic vision captures only a fraction of the information contained within the spectra of stimuli in the natural visual world. Factor analysis of spectra from a range of objects under a range of lighting conditions indicates that to capture most of the spectral variation would require six or seven distinct photopigments and additional color dimensions [8].

Notably, higher-dimensional spaces are observed in species of reptiles and birds. The three-dimensionality of human color vision suggests that additional photopigments bestowed no advantage over the course of human evolution, i.e., the differences among metamers were not significant in the ecological niches occupied by prehuman primates.

The majority of mammals make do with dichromatic color vision, having only two cone classes. This in turn implies that trichromatic vision *was* adaptive for some primates, with evolution selecting for the divergence of L- and M-photopigment genes. Several adaptive advantages have been advanced to account for this feature of human color space. The difference between M and L cones allows normal trichromats to detect red objects against green backgrounds. In particular, ripe fruit stands out against foliage, as do older, more digestible leaves [9]. Further speculative benefits from the red-green dimension of color space include social signaling, a sexual selection role, and preserving color constancy under changes in lighting conditions [8].

Abnormal Color Space

Color space is convenient for representing the effects of color vision deficiencies (CVDs).

Depending on the specific form of deficiency, two colors may be harder to discriminate (i.e., perceptually more similar) when they are separated along a particular direction in the space. This characteristic direction – running between red and green, for the common forms of CVD – is the *confusion axis*. Thresholds for distinguishing between a reference hue and small variations of it are increased in this direction (e.g., slightly redder and slightly greener versions). The locus of hues that are just noticeably different from the reference, which would form a circle when plotted in a suitable color plane, instead becomes an ellipse elongated along the confusion axis.

Alternatively, one could say that the *personal* color space for a CVD observer is compressed, reducing distances along the confusion axis. The degree of compression corresponds to the severity of the deficit. This interpretation underlies the design of widely used panel tests for CVDs. In the extreme case where an entire class of photoreceptor is absent, color space becomes two- rather than three-dimensional, and the color circle collapses to a line. The principle is supported by numerous studies where MDS reconstructed personal color spaces for individuals with CVDs.

Color Terms

As seen above, color space provides a framework for analyzing color language. For a given *Basic Color Term* (BCT), the range of hues to which that term can be ascribed (its extension) comprises the corresponding *Basic Color Category* (BCC). The BCC can be treated as a geometrical domain by mapping that range into color space.

Each BCC is circumscribed by its boundaries with adjacent color categories. “Red,” for instance, has boundaries with the domains of “pink,” “orange,” “purple,” and “black.” On one side of the “watershed,” a stimulus might be labeled more often than not as “red,” whereas a second stimulus, nearby in color space, might attract “pink” as the majority name. Thus, the continuity of color is *partitioned* into color-category domains. There are four points to note here:

1. The vicinity of a category boundary creates *categorical perception* effects in perceptual tasks. These effects are vitiated by verbal interference, indicating that language plays some role in them.
2. For English, the partition is *complete* in the sense that the category domains cover color space in its entirety; there is an applicable term for any realizable color. This is not necessarily the case in every language.
3. Empirically, the domains of English color categories are *connected* and *convex*. That is, there are no situations where two hues receive the same color term but have some hue between them in color space which is labeled with a different term. In particular, there is no term with a domain separated into two non-contiguous parts.
4. The boundaries of a BCC are part of the BCT's definition, between them circumscribing the hues that it can label. They are not *all* of its definition, however. A color term is also characterized by its *focal hues*, i.e., the hues picked out from the color gamut as prototypal best examples. One may also define the BCC "centroid" hue, the "center of mass" or mean location of its domain in color space.

So far the requirements for a color term to be "basic" have not been spelled out. One criterion have been assumed implicitly: a BCT must be understood by almost all speakers of a language, with consensus about its meaning, i.e., few disagreements or misunderstandings resulting from divergent usage. A second criterion is that to be a color term at all, a word must generalize across semantic domains and be applicable to any arbitrary object, as opposed to words like "roan," "palomino," and "dun," specific to animal coats.

In English, 11 color words are BCTs, 3 achromatic terms, and 8 chromatic terms: black, white, gray, red, pink, orange, yellow, brown, green, blue, and purple.

English also provides a rich vocabulary of *subordinate* color terms. Some of these are compounds, generated from a BCT and made more specific by modifying it with a qualifier, e.g., "dark blue" or "bluish green," or with a noun as

exemplar, e.g., "sky blue." Others are derived directly from specific objects or pigments (e.g., "lilac" or "magenta"). That is, to use them is to use an implicit metaphor ("lilac colored"). A third criterion for BCTs is that they must not be compounds or still linked to a noun and carrying its connotations. This third criterion requires some care. The BCT "orange" arose from the name of the fruit, but the metaphor has become so routine that it is now a separate word with no citric associations in the minds of speakers.

However, the distinction between basic and subordinate terms is not clear-cut. Rather, "basicness" is a continuous gradient along which can be located by examining their usage, generative properties, etc. [10].

Color terms tend to form a nested, hierarchical pattern, with a broader basic term (*hypernym*) divisible into qualified, more specific *hyponyms*. There are exceptions, color being a continuum rather than a structure of nested boxes, and a number of subordinate terms straddle the borders between BCTs. "Turquoise" and "teal" lie between "blue" and "green" and are more specific than either, though speakers may argue about their exact usage.

Primary and Secondary Terms

Among the BCTs, a distinction is sometimes drawn between *primary* and *secondary* terms. The former are the six "cardinal hues" comprising the three oppositions of the Hering opponent-hue scheme. Primary terms lend themselves to "unique hue" judgments (see chapter ► "Unique Hues"). "Unique green," for instance, is a wavelength that is seen as "green" on its own with no admixture of "blue" or "yellow." Secondary terms are derived from overlaps or intersections of primaries. Three of them – orange, purple, and pink – are the intersections between "red" and its primary neighbors "yellow," "blue," and "white," respectively. "Brown" is the overlap between "yellow" and "black," while "gray" occupies a middle ground between the achromatic extremes of "white" and "black." However, the putative primary/secondary distinction does not appear on the basicness scale as an obvious jump. In addition, it leaves unexplained why some of the terms for

primary-term intersections are basic, while others (e.g., turquoise) are subordinate.

Primary terms are featured in the *color-naming task*. Here observers characterize a series of briefly presented stimuli using a constrained list of options. A 590-nm light, for instance, might be described as “red with some yellow” (or “70% red, 30% yellow”). Repeated exposures build up the precision of the description. The procedure allows subtle nonlinearities in color vision to be quantified, such as the Bezold-Brücke effect (the changes in chromatic content of a colored light as it becomes more intense). In this context, observers are comfortable with describing hues as combinations of “red” and “yellow” when a secondary term such as “orange” is not an available response. This contrasts with the situation when a primary term such as “blue” is absent from the options; observers prefer to leave that component of the stimulus appearance unlabeled (“none of the above”).

Color vocabulary becomes more finely divided in the course of language acquisition from childhood to maturity. One might expect primary terms to be learned earlier than secondaries, but the evidence for a standard order of acquisition is equivocal [11]. Cultural factors are involved, with a historical drift toward acquiring terms at an earlier age.

Ontological Status

The ontological status of the BCTs and the categories of experience they represent are still unclear. Are the qualities of “redness” and “blueness” part of the basic genetic patrimony of every human, hardwired into human brains (as the *universalist* position has it)? To what extent is the genetic endowment modified by formative visual environment and cultural factors (specifically, the color lexicon of one’s first language)?

A number of MDS studies have elicited judgments of dissimilarities among pairs of color *terms* rather than pairs of hues. The resulting solutions, in which the BCTs are embedded in a *conceptual* color space, show no substantial differences between languages (e.g., English and Mandarin) or from perceptual MDS models [12]. Notably, color-deficient informants

internalize the normal relationships within color space such as the diametrical opposition between “red” and “green” [13]. That is, they are intellectually aware of color relationships that they have not detected from observation. MDS has also been applied to *empirical* relationships among BCTs, using the number of samples on the boundary between two BCCs as the index of their similarity.

The issue has inspired comparisons with non-English and non-European languages. It early became evident that many cultures do not emphasize hue as a topic of discussion to the same extent as English. Many languages do not distinguish “color” from other qualities of surface appearance such as lightness, sheen, or texture: depending on context, words may refer to color or some other visual effect. A notable example is the difficulty of translating putative color adjectives in the *Iliad* from Homeric Greek into consistent English equivalents. In other languages, terms may have chromatic applications but are enmeshed in a web of cultural connotations.

Systematic cross-cultural research requires a standardized palette of hue samples. Informants are presented with each sample in term and asked to identify its color. One such palette, the Munsell array, has been featured in the *World Color Survey* and the *Mesoamerican Color Survey* and in numerous studies of individual cultures (see chapter ► “[World Color Survey](#)”).

The methodology is open to critiques, by presupposing for each culture an interest in color as a concept and the presence in each language of color terms per se – neither domain specific nor carrying primarily non-chromatic meanings [14]. That is, it presupposes what it purports to discover, imposing a modern English/European conceptual framework and only capturing those aspects of color discourse that fit. Thus, results from this research tradition may underestimate the prevalence of “non-partition” languages where some colors go unlabeled.

Bearing this caveat in mind, the WCS found the number of BCTs to vary widely across languages, making finer or coarser chromatic distinctions. Thus, many languages subsume “blue” and “green” within a broad “grue” term (some “grue languages” possess a word equivalent to “purple,”

in further evidence against the primary/secondary distinction). There is, however, a cross-cultural consensus about the focal hues and “centroid hues” of the BCTs. A language may have fewer BCTs than English, but the prototypal examples of their BCCs are generally close to an English equivalent [15]. Moreover, these linguistic distinctions are *prioritized*, in the sense that some are never made unless other “earlier” distinctions have been made already (for instance, if a language marks only three color categories, these will be “dark colors,” “light colors,” and “red”). These sequence relationships define a “Berlin-Kay sequence” (see chapter ► “Berlin and Kay Theory”).

There is clearly a special status for BCTs. Several explanations for their cross-cultural nature have been advanced [4, 16]. At the same time, CP effects on color-similarity judgments vary between languages, depending on the boundaries between BCCs. These boundaries necessarily shift with the size of the color lexicon but can differ even between languages with the same number of color terms.

Psychological primary colors

Definition

Psychologically pure colors are colors that exhibit a homogeneous appearance on some dimension of perceived color. Purity of appearance is closely tied up with theoretical understandings of the three canonical color attributes of hue, saturation, and lightness. According to the dominant Hering opponent color framework, the hues red, green, blue, and yellow are distinctive and fundamental to all hue perception, in part due to the fact that they admit of pure or unique variants and all other hues (such as orange) appear as mixtures of them. Saturation and related notions are characterized essentially in terms of purity, involving judgments regarding differences in the appearance of chromatic stimuli and achromatic stimuli. Highly saturated colors appear to have low achromatic content or to be more intensely chromatic. In the achromatic domain, the lightness dimension runs from light to dark. The corresponding extreme ends of that dimension, white and black, have an appearance that wholly excludes the other, while intermediate steps between them are grays that appear to be mixtures of black and white. The concept of purity plausibly could also be usefully applied in connection with other ways of categorizing perceived color, e.g., warm versus cool and positive feeling versus negative feeling.

Overview

The concept of subjective purity figures in discussions of the three attributes of perceived color

around which the bulk of contemporary theorizing is organized: hue, lightness (value), and saturation (chroma). For hue, the apparent purity of certain hues has played a central role in the development of the dominant perspective on the structural relations among the hues: Ewald Hering's opponent colors theory [1]. In Hering's theory, hues are denominated by terms such as "red," "blue," "green," and "yellow"; note that the terms used to refer to hues from the standpoint of theorizing about color experience need not reflect the color terms or concepts employed by particular perceivers or groups of perceivers. According to Hering's conception of the hues, the four hues just named have a special status as *primary* hues. They are supposed to be psychologically basic elements out of which all hue sensations are constructed. The primary hues are hypothesized to be arranged along two independent axes, red/green and blue/yellow. This opponent structure is thought to explain phenomenological observations about the purity of some hues and the mixed appearance of others, as it allows for *unique* percepts of each primary hue and *binary* combinations of primary hues not on the same axis. Purity is the essential criterion for being a unique hue, as unique hue percepts are those that consist entirely of a single primary hue. For example, while most greens are either bluish or yellowish, unique green is the shade of green that is perceived as having no tinge of either blueness or yellowness to it. By contrast, orange is a binary hue, always perceived as some blend of redness and yellowness, while turquoise is seen as a combination of greenness and blueness. It is important to emphasize that the purity of the unique hues and the impure nature of binary hues are thought to be phenomenologically present in experience.

Regarding the unique hues, their apparent purity goes hand in hand with their perceptual salience and the privileged status of the Hering primaries as elemental hue sensations. As for binary hues, they are said to look to contain proportions of their component primaries and to not be perceived as unanalyzable, integral wholes formed from the primaries. The experimental literature on hue scaling fits with the preceding phenomenological observations and Hering's

opponent colors theory. Subjects in these studies have no little or no difficulty understanding the task instructions and can produce judgments about hue content for all hue stimuli using only the Hering primaries (in permissible combinations for nonunique hues) and which total to 100%, with unique instances of the Hering primaries excluding all other hues [2]. To be clear, there is considerable variability across subjects when it comes to which particular stimuli are designated as instances of the unique hues [3]. The binary hues seem completely unsuitable for use in a hue scaling task, and the subjective purity of, say, unique blue makes it absurd to ask subjects to judge what proportions of purple and turquoise (or red and green, for that matter) look to be in it.

The color appearance of achromatic stimuli (i.e., those with no hue content) varies along the lightness dimension between the extremes of black and white, with a gradient of shades of gray in between. Subjective purity goes along with those achromatic extrema in much the same way it does with the unique hues. The apparent purity of whiteness has long been of cultural significance, and distinctions are commonly made between pure and impure whites. The concept of absolute or pure black has also aroused much interest, and artists for centuries have consciously sought to avoid pure blacks when rendering natural scenes. That black and white have a perceptual salience akin to that of the unique hues is evident in the fact that samples of them used in the World Color Survey received by far the most selections as “best examples” of basic color terms across all participants from the 110 languages surveyed [4]. Hering took white and black to be psychologically basic (and opposed) color sensations on a par with the primary hues. He also proposed a measure of color purity stated in terms of proportions of whiteness, blackness, and primary hues perceived in a stimulus [5].

Saturation and related notions inherently are purity concepts that involve the perceived difference between a chromatic (i.e., hue-bearing) stimulus and an achromatic stimulus. Highly saturated colors appear quite vivid and more “full” of their component hue than do less saturated colors. As with hue, scaling procedures are available for

saturation, with subjects making judgments about the chromatic purity of stimuli in terms of the percentages of their total color sensations that are chromatic and achromatic [2].

While not an essential commitment of views like Hering’s that account for color phenomenology in terms of red/green, blue/yellow, and white/black axes, throughout the last 100 years, it has been common to believe or hope that those axes have a direct neurophysiological realization. Although caution is in order when allowing phenomenology to influence neurophysiological theorizing, the apparent purity and perceptual salience of the unique hues, white, and black make it natural to suppose that they must have some correspondingly distinctive neurophysiological underpinning. With respect to perceived hue, a familiar idea is that there are separate, independently operating red/green and blue/yellow neural “systems” or “channels,” the combined outputs of which account for the particular unique or binary hue appearance encountered in experience. For example, unique green is seen when the blue/yellow system is nulled and the red/green system points to green, while a purple sensation arises when the red/green and blue/yellow systems are tipped toward red and blue, respectively. It should be pointed out that this theoretical perspective need not endorse a necessary connection between any particular kind of neural activity and any particular kind of color phenomenology across all perceivers. Rather, what matters is that each individual perceiver has her own personal profile of neural responses such that the hypothesized red/green and blue/yellow systems can exhibit the suggested null and non-null activity. In any event, the idea that subjective purity has a direct neurophysiological grounding is complicated by a range of empirical findings regarding inter alia the characteristics of color-opponent processing cells in the visual system [2, 6, 7].

Despite purity being so important to the understanding of key attributes of color experience, appeals to it have not gone unquestioned. For example, in the early part of the twentieth century, Carl Stumpf rejected saturation as a basic attribute of perceived color on the grounds that it is, rather than a perceptual characteristic pertaining to the

chromatic purity of a sensation, a cognitive abstraction that involves a comparison between a perceived color and some ideal of it [5]. Saturation and its brethren clearly have had a vexed history. However, perhaps the most interesting concerns voiced about appeals to subjective color purity concern the possibility that its application has been overly restricted in treatments of hue. Such worries ultimately touch on the basic motivations for the deeply entrenched Hering opponent colors theory.

In the philosophical and empirical literatures on color, statements that echo the remarks above about the essentially mixed appearance of binary hues are widespread. However, expressions such as “pure purple” and “pure orange” can be heard in everyday conversations and are invoked in artistic and commercial settings. It is certainly easy to find paints and other products with such labels. Some scientists and philosophers have also disputed claims about the necessarily mixed appearance of all hues other than the unique Hering primaries. They contend that their own phenomenological reflection on hues such as orange and purple reveals that there are also pure variants of them, e.g., a pure purple that does not look to contain any blue or red [8, 9]. Others have objected that empirical results concerning unique hue judgments that seem to support the thesis that the binary hues have a subordinate status to the Hering primaries are an artifact of the instructions given to participants. The alternative suggestion is that a minor modification of those instructions would lead subjects to find hues such as “unique orange” and “unique turquoise” that are just as subjectively salient as the unique Hering primaries [10].

As was observed above, the form of purity relevant to the unique/binary hue distinction is perceptual (psychological), not physical or otherwise objectively assessable. This, together with the heterodoxies just noted, invites the possibility that different perceivers may have either (i) different criteria for what counts as a pure hue percept or (ii) fundamentally different kinds of structure to their color experiences that either allow or forbid the possibility of hues such as

pure orange. Both are potential sources of experimental or theoretical confusion, as well as interesting topics of study in their own right. Another idea worth considering, likely in connection with (i), is that the frequency of pronouncements regarding the mixed appearance of all purples (oranges, etc.) is due to the pervasive influence of the Hering opponent colors theory on scientific and philosophical discussions of color. The attractively tidy picture the Hering theory offers of both psychological and neurophysiological aspects of color vision certainly could affect not only how experiments are constructed and their results are interpreted but also how individuals construe their own phenomenology. It has already been pointed out that empirical difficulties confront attempts to find neurophysiological mechanisms mirroring the hypothesized opponent hue axes of Hering’s model of color phenomenology. Further research open to the possibility that purity in hue perception might not be restricted to red, green, blue, and yellow could present a serious challenge to the phenomenological tenets that make Hering’s theory such an appealing account of color perception.

At a minimum, it appears that there is a need to further sharpen the criteria for what should count as a pure color percept, if matters such as those just noted are to be resolved. Of course, what is to be made of the construct of “psychologically pure colors” depends on how psychological color is understood. That, in turn, may have important consequences for the role played by the notion of purity. For example, certain (lexical, practical, emotional, etc.) categories that are associated with color plausibly could affect or facilitate judgments of purity in various ways. Potentially in play here are distinctions that go beyond the sort of structural relations among the hues that figure in Hering’s theory, such as “dessicated” versus “moist,” “hot” versus “cold,” or “positive feeling” versus “negative feeling” colors; see Schloss and Palmer’s entry on color preference. It may therefore be appropriate to consider that subjective color purity is not univocal but rather is highly dependent on the task used to assess it and thus should be defined in each circumstance of use in

terms of the particular parameters of its empirical assessment.

Purkyně, Jan Evangelista

Michal Vik¹ and Renzo Shamey²

¹Faculty of Textile Engineering, Laboratory Color and Appearance Measurement, Technical University of Liberec, Liberec, Czech Republic
²Color Science and Imaging Laboratory, College of Textiles, North Carolina State University, Raleigh, NC, USA

Biography

Jan Evangelista Purkyně (Fig. 1) was born sometime between 17 December and 19 December 1787 in the castle in Libochovice near Litoměřice, Bohemia (then part of the Austrian monarchy) and now Czech Republic [1]. Purkyně died on 28 July 1869.

Purkyně, Jan Evangelista, Fig. 1 Purkyně, Jan Evangelista (1787–1869)

He was the oldest son of Josef and Rozálie (born Šafránková) Purkyně. His father worked as the chamberlain of Libochovice manor. Jan learned to observe nature and people initially from his father, who used to take him on business trips. He inherited diligence and discipline and also a sense of humor from his mother. Jan began to read early and was introduced to Komenský's publication *Orbis Pictus*. He also learned to read Latin and Greek texts from a priest called Schiffner in Libochovice.

In 1793, Purkyně's father died and Rozálie was left with her two sons Jan and Josef. With assistance from Rozálie's friends, Jan was enrolled at the Piarist Grammar school. After graduation from the grammar school (1804) and upon recommendation of his teachers, Jan went to a monastic house in Dobrá Voda. Due to his excellent performance, he managed to complete the 3-year program in 1 year. He then started to teach at the lower grammar school in Strážnice, and from there, he went to teach at the Piaristic Institute in Litomyšl. There, he devoted himself to the study of philosophy and history and poetry and became a devoted fan of the classical German philosopher F. W. Schelling.

In 1807, Jan returned home, but in the fall of the same year, he started to study philosophy in Prague University. He had to leave his studies after the third year because of financial reasons and accept to teach Baron Hildprandt's son Ferdinand in Blatná. With Hildprandt's financial support, Jan went back to Prague in 1812 to study medicine.

Upon completion of his medical program, he unsuccessfully applied to several faculty positions including professor of pharmacology in Prague, professor of anatomy and physiology in Graz, and professor of anatomy in Ljubljana.

In 1822, he secretly traveled to Germany and was introduced to Schultz and subsequently met with Goethe. In 1823, and upon the recommendation of Goethe, the Prussian king signed a decree which nominated Purkyně a professor in Physician School of Wroclaw (Breslau in Prussia) where he continued his research. There he lectured physiology, eye pathology, and psychology, but his lectures were not well attended. He

continued his study of subjective visual perception and published a comprehensive work on this topic which was dedicated to Goethe. In 1826, he was accepted as a Masonic Trainee in Berlin, 1 year later as Journeyman and subsequently as Master. In 1825, he published his work "Neue Beiträge zur Kenntnis des Sehens in Subjektiver Hinsicht" (Reimer, Berlin, pp. 109–110), which earned him the eponymy Purkinje effect (or Purkinje shift) [2].

In 1827, Jan Evangelista Purkyně (a protestant) got married to Julie Anežka Rudolphi (a catholic) in Berlin, and they kept their respective denominations. With Julie, he had two daughters and two sons. Both of his daughters died of cholera. Purkyně became a member of the Leopoldine science academy in 1829. In 1830, he became a professor of botany at Wroclaw University. In 1834, his wife died, leaving Purkyně with two young sons. He did not remarry.

Purkyně turned his focus to botany and was awarded the Montyon Prize in France for his monograph "De cellulis antherarum fibrosis nec non de granorum pollinarium formis" in 1833. In 1836, the State Secretary accepted Purkyně's suggestion for the establishment of a physiological institute (the first in Central Europe). In 1849, Purkyně was called back to Prague as a professor by the emperors' decree. Purkyně was later nominated as a member of London's King Society. Purkyně was also honored as the guardian of *Malice česká* – a committee for edification of language and literature from 1852 to 1858. Thanks to Purkyně, the first Czech industry school (1857) was also opened in Prague where he became the principal from 1857 to 1859. His house was also a place where many Czech artists met and discussed work.

Major Accomplishments/Contributions

Subjective Visual Phenomena (1818–1825)

Jan Purkyně was one of the best known anatomists and physiologists of his time. He was probably one of the early pioneers of what we now call vision science. As a medic, Purkyně studied differences in subjective visual phenomena

including lightshade, galvanic and vassal patterns (embranchment of vassals in his own eye), glare patterns, subjective feelings in darkness (phosphenes), blind spot, unity of both eyes' visual fields, double sight, indirect sight, colorblindness in peripheral retina, light patterns, and afterimages. Probably, one of the most well-known contributions of Purkyně to color and vision science is that which bears his name, the Purkyně effect.

As a medical student during spring walks through the flowering countryside, Jan observed that after the sunset, the color of flowers appeared to change; red blossoms appeared darker, yellows faded, and the blues seemed brighter. Purkyně studied this phenomenon systematically and found out the same results with other object colors. That is, under decreased illumination, blue colors appeared lighter than reds. He focused his studies on this topic, and in 1818, he defended his dissertation in the faculty of medicine on "Contributions to the knowledge of sight from a subjective sense" [3]. The effect is shown in the picture of blue and red flowers simulated under three illumination conditions: average (when cones are active), dim (when rods intrude), and dark (when cones become mostly deactivated). This phenomenon is due to the contribution of rods on the perceived color of the scene. Rods require low levels of illumination to become activated (and are associated with night vision), whereas cones are activated at much higher levels of illumination (and are associated with day and color vision). Under certain conditions, e.g.,

during dawn or dusk, there is just sufficient illumination to activate cones, but illumination is low enough to activate rods also. If the contribution of rod signals to the overall image and thus the perceived color exceeds about 10%, the effect becomes known as rod intrusion. Since rods' peak sensitivity is around 496 nm, which is much closer to the peak sensitivity of the short-wavelength-sensitive cones (responsible for blue colors at 419 nm) compared to that of long-wavelength-sensitive cones (responsible for red colors at 558 nm), the overall perception of the observed scene is shifted toward blue at low levels of illumination when rods become activated. Therefore, blue colors appear brighter, whereas red colors appear very dull and almost black (Fig. 2).

Objective Eye Examination Techniques (1823)

Purkyně recommended a technique for systematic objective examination of eyes using reflective pictures. In this process, candle flame mirrors on the front and back of the cornea and then on the front and back of the retina. Purkyně examined the possibility of using reflective pictures to measure the curvature of cornea (which became the principle of keratometry and ophthalmometry) and its use in diagnosis of eye diseases and defects [4]. After many years, Purkyně obtained an achromatic Plossl microscope, which he placed in his own apartment since he did not have a suitable place within the university. He was deeply interested in the stomach's mucosa structure and discovered stomach glandule. He also observed eye

under low levels of illumination levels, the *blue* colors appear much brighter compared to *red* ones

luminescence and the possibility of observing eyes' background in vivo, a principle of ophthalmometry which was later established by Helmholtz in 1850 [5].

Semiconductor nanocrystals

Definition

Quantum dots are zero-dimensional nanoparticles (defined as materials of which all dimensions are smaller than 100 nm) with electrons or holes confined in three dimensions. Typically, the size of quantum dots ranges from 1 nm to 10 nm, which are made up of hundreds of atoms. Quantum dots have unique properties due to the quantum confinement effect. Their absorption and emission spectra shift to higher energy, that is, shorter wavelength, as the size of quantum dots decreases. Therefore, the photoelectronic properties can be adjusted by changing the size and composition of quantum dots.

Quantum Confinement Effect

The continuous energy band becomes quasi-continuous or discrete when the size of quantum dots is close to or less than their exciton Bohr radius. As the size decreases, the carriers, including electrons and holes, will be confined and the kinetic energy increases. Consequently, the band gap of quantum dots increases, and the absorption and emission spectra shift to higher energy, which is also called blue shift.

Classification of Quantum Dots

Quantum dots can be categorized into II–VI group (ZnS, ZnSe, CdS, CdSe, CdTe), III–V group (InP, InAs), IV–VI group (PbS, PbSe), I–III–VI group (CuInS, CuInSe), and IV group (C, Si) by their composition. Up to now, quantum dots containing Cd have been most developed such as CdS and CdSe quantum dots, which have been used in quantum dot TVs.

Mechanism of Luminescence

The luminescence of quantum dots is induced by the radiative recombination of excited electrons and holes in the semiconductor materials. Electrons in the valence band of quantum dots transit to the conduction band when excited by photons and

become “hot carriers,” leaving a hole in the valence band [1]. The hot carriers may either relax to the band edge, forming excitons (electron-hole pairs), or they may be trapped by the surface defects. Then the excitons may emit photons through radiative recombination or emit Auger electrons or phonons through nonradiative recombination.

Properties of Luminescence

- Wide excitation spectrum
- Wide tunable emission spectrum
- High color purity of emission
- High quantum yield of fluorescence
- Tunable fluorescence lifetime
- High light stability and high resistance to photobleaching (Fig. 1)

Synthesis

Quantum dots can be synthesized through physical or chemical methods. The physical methods include molecular beam epitaxy and physical vapor deposition, but the colloidal chemical synthesis is most widely used at the present time. It can be based on water or organic solvents. Furthermore, there are many factors that can affect the synthesis process, such as the temperature, reaction time, and concentration of the precursors.

There tend to be surface defects for quantum dots of small size where nonradiative recombination can happen. As a result, surface modification is used to reduce the surface defects and hence increase luminous efficiency (Fig. 2).

Energy Band Engineering

The band gap of quantum dots can be tuned through changing their size. It may work well in terms of Cd quantum dots, but it is not a panacea for all the quantum dots. Energy band engineering is thus developed these years. The band gap of quantum dots can be tuned by means of forming core-shell structure, alloying, and doping.

Applications

Quantum dots are promising in many applications such as quantum dot light-emitting diodes (QD-LEDs) [2], fluorescent probes [3], quantum dot solar cells [4], and photocatalysts [5].

Quantum Dot Light-Emitting Diodes

Quantum dots have been broadly used in photo-electronic devices due to their tunability, high quantum yield, and stability. Quantum dot LEDs can be divided into two types: electroluminescence and photoluminescence. In the electroluminescent devices, quantum dots are used as the emitting layer in the LEDs. Electrons and holes combine in the quantum dot emitting layer under external electric field, after passing the electron transport layer and the hole electron transport layer respectively. For photoluminescent devices, white light can be obtained by exciting quantum dots instead of traditional rare earth phosphors with UV or blue light chips (Figs. 3 and 4).

Fluorescent Probes

Quantum dots have been used as fluorescent probes in the fields of biology, medicine, and

Quantum Dots,

Fig. 1 Photographs of quantum dots irradiated by UV light

Quantum Dots,

Fig. 2 Schematic representation of colloidal chemical synthesis of quantum dots

Quantum Dots, Fig. 3 Schematic representations of quantum dot LEDs [6]

analytical chemistry. For example, quantum dots of high biocompatibility can be used in in vivo imaging or real-time tracking of molecules because of their higher brightness and stability compared with traditional organic dyes. Quantum dots can also be used for detection of ions and molecules based on specific chemical reactions, fluorescence resonance energy transfer, inner filter effect, or other theories.

Quantum Dot-Sensitized Solar Cells

Typically, quantum dot-sensitized solar cells consist of photoelectrodes (e.g., titanium dioxide), conductive glass, quantum dot sensitizers, and electrolytes. Quantum dots are excited by sunlight, producing electron-hole pairs. The electrons are injected into the conduction band of the semiconductors and then to the out circuit. The oxidized electrolytes get electrons and are reduced.

Quantum Dots, Fig. 4 Photographs of quantum dot LEDs

Then the quantum dots are reduced by the reduced electrolytes and hence the original quantum dots are regenerated.

Photocatalysts

Some quantum dots, for example, ZnO, are often used as photocatalysts owing to high specific surface area and thus more active sites for photocatalysis. The quantum dots are excited by the light and produce electron-hole pairs. The electrons react with water and oxygen so hydroxyl radicals and superoxide anion radicals that can oxidize organic compounds. Rare earth ions can be doped into ZnO quantum dots to expand the active area of photocatalysis and lower the recombination rate of electron-hole pairs, which facilitates the process of photocatalysis.

Other Applications

In the fields of lasers [7], photodetectors [8], visible light communication [9], and confidential information collection [10], quantum dots have also been widely researched and utilized.

Definitions

Rayleigh scattering refers primarily to the elastic scattering of light from atomic and molecular particles whose diameter is less than about one-tenth the wavelength of the incident light.

Rayleigh line refers to the unshifted central peak observed in the spectroscopic analysis of scattered light.

Mie scattering refers primarily to the elastic scattering of light from atomic and molecular particles whose diameter is larger than about the wavelength of the incident light.

Thomson scattering is elastic scattering of light from free electrons.

Raman scattering is inelastic scattering of light from objects whereby the scattered photon has a lower (Raman Stokes scattering) or higher (Raman

anti-Stokes scattering) energy than the incident photon.

Introduction

From ancient times, people have gazed up at the sky in daylight and asked the perennial question “Why is the sky blue?” [1]. Other similar and related questions are “Why is the night sky black?,” “Why are sunrises and sunsets red?,” and “Why are the clouds white?” Rayleigh [2–5] and Mie scattering [6] lie behind the long-sought answers to all such questions about the colors seen in the sky.

The phenomenon called Rayleigh scattering is named after its discoverer, John William Strutt, 3rd Baron Rayleigh (Fig. 1), a physicist who is known for a number of significant scientific discoveries that he made toward the end of the nineteenth century including the discovery of argon, an achievement for which he earned the Nobel Prize for Physics in 1904. However, the use of the term “Rayleigh scattering,” in general, and also “Rayleigh line,” in specific use in light

scattering spectroscopy, has been controversial in the past and has led to some confusion [7]. These nomenclature issues will be clarified in the following discussion.

It is also noteworthy that Rayleigh contributed widely to scattering theory in eight different categories; for an overview of these different contributions, see Twersky [8]. However, this entry is limited to a description of classical Rayleigh scattering of light from single small objects such as molecules and atoms. Thus, it is ignoring coherence effects that arise in solids, liquids, and gases at atmospheric pressure or even free electrons where it is known as Thomson scattering.

The scientific history behind the development of the term “Mie scattering” or “Mie theory” is convoluted [9]. Mie theory solves one of the most important problems in optics – the absorption and scattering of light by a small sphere of arbitrary size and refractive index. In 1908, Gustav Mie (Fig. 2) published his now famous paper on the simulation of the color effects connected with colloidal gold particles [[6] wherein he applied

Rayleigh and Mie Scattering, Fig. 1 Lord Rayleigh (1842–1919) ca. 1870

Rayleigh and Mie Scattering, Fig. 2 Gustav Mie (1868–1957)

Maxwell's electromagnetic theory to calculate light scattering from small spherical particles. He was not the first to perform this calculation, as similar investigations were also carried out and published earlier in 1863 by Alfred Clebsch and in 1890 by Ludvig Lorenz and soon afterwards in 1909 by Peter Debye [9]. However, Mie was the first to apply Maxwell's equations to find a solution and his name is now firmly attached to the theory, which is sometimes also called Lorenz-Mie theory and Lorenz-Mie-Debye theory.

Classical Description

Rayleigh treated the scattering of light by a spherical particle, whose diameter is much smaller than that of the wavelength of light. It is generally accepted that this size regime applies for particles (or molecules) of size less than 1/10th the vacuum wavelength, λ , of the incident light. Rayleigh considered a plane wave incident on a dielectric sphere of radius r and of relative permittivity (dielectric constant) ε , as illustrated in Fig. 3 [10]. The probability that the sphere scatters light at angle θ is proportional to the differential scattering cross section, $d\sigma(\theta)/d\Omega$, which is defined as the ratio of the power scattered into the solid angle $d\Omega$ between θ and $d\theta$ (Fig. 3) to the incident power per unit area. For unpolarized

incident light, the differential cross section becomes [10].

$$d\sigma(\theta)/d\Omega = (1/2) \times (2\pi n_0/\lambda)^4 r^6 \left[\frac{(\varepsilon - \varepsilon_0)}{(\varepsilon + 2\varepsilon_0)} \right]^2 (1 + \cos^2\theta), \quad (1)$$

where ε_0 is the relative permittivity and n_0 is the refractive index of the medium surrounding the sphere of refractive index n . Integrating this equation over the entire solid angle yields the total cross section:

$$\sigma_R = (8\pi/3) (2\pi n_0/\lambda)^4 r^6 \left[\frac{(\varepsilon - \varepsilon_0)}{(\varepsilon + 2\varepsilon_0)} \right]^2. \quad (2)$$

The intensity I_R of the Rayleigh scattered light is given by [11]

$$I_R = I (2\pi n_0/\lambda)^4 (r^6/2D^2) \times \left[\frac{(\varepsilon - \varepsilon_0)}{(\varepsilon + 2\varepsilon_0)} \right]^2 (1 + \cos^2\theta), \quad (3)$$

where I is the intensity of the unpolarized incident light and D is the distance between the particle and the observer.

It is now possible to explain why the sky overhead looks bright blue as illustrated perfectly in Fig. 4 that shows Rayleigh scattering of sunlight

Rayleigh and Mie Scattering, Fig. 3 A plane wave polarized in the x - z plane is incident on the dielectric sphere from the left along the z direction. The arrows on the sphere denote the polarization of the dielectric material. Part of the scattered wave is shown scattered between angle

θ and $\theta + d\theta$. (Reproduced with permission from A.J. Cox, A.J. DeWeerd and J. Linden, *Am. J. Phys.* 70, 620–625 (2002). Copyright 2002, American Association of Physics Teachers)

giving rise to the intense blue color of the sky in a photograph of Dante Alighieri's effigy in Florence, Italy. Equation 4 indicates that the Rayleigh scattering intensity varies as the fourth power of the inverse wavelength of the incident light. This

Rayleigh and Mie Scattering, Fig. 4 Dark blue skies overhead in Florence, Italy: Statue of Dante in the Piazza di Santa Croce in Florence (Enrico Pazzi, 1865). (Copyright Lilia R. Lockwood)

is known as Rayleigh's law. For example, the intensity of Rayleigh scattering at 400 nm in the blue part of the visible spectrum is higher by a factor of 9.38 compared with that at 700 nm in the red portion of the spectrum. So, when considering Rayleigh scattering of visible sunlight from molecules in the air, it is clear that blue light will be brighter than red light. Conversely, at sunset, when the sunlight travels further through the Earth's atmosphere, more blue light is scattered out of the beam path than red light, so the sunset glows red (Fig. 5). The $(1 + \cos^2 \theta)$ term in Eq. 3 contains the angular dependence of the scattering and indicates that Rayleigh scattering intensity at 90° is one-half that in the forward or backward directions.

For particle sizes larger than λ , Mie scattering predominates [6, 12], and for particles that are much larger than λ , a third type of atmospheric scattering, known as nonselective scattering, occurs [13]. A description of this last type of scattering, which can be considered as comprising a combination of Mie scattering, absorption, and multiple scattering, is outside the scope of this entry. Nonselective scattering is not wavelength dependent and is the primary cause of haze in the lower atmosphere. Water droplets and large dust particles can cause this type of scattering.

A mathematical description of the physics of Mie scattering is the result of a considerably more complicated calculation than that needed for Rayleigh scattering [12]. The calculation involves

Rayleigh and Mie Scattering, Fig. 5 This photograph of the sunset seen through clouds illustrates both Rayleigh and Mie scattering. (Copyright Terry D. Cyr)

considering a plane wave incident on the sphere and a spherical scattered wave. The total scattering cross section, σ_M , can be expressed in the form of an infinite series as [10]

$$\sigma_M = \left(\frac{\lambda^2}{2\pi n_0^2}\right) \sum (2m+1) \times \left(|a_i|^2 + |b_i|^2\right), \quad (4)$$

where the summation is from $i = 1$ to infinity and the coefficients a_i and b_i are expressed in terms of spherical Hankel functions and spherical Bessel functions of the first kind; these functions are dependent on the magnetic permeabilities of the sphere and surrounding medium and the values of parameters $m = n/n_0$ and $x = 2\pi n_0 r/\lambda$, which is termed the size parameter.

Representative results from calculations of the Rayleigh and Mie scattering cross sections using Eqs. 2 and 4, respectively, are shown in Fig. 6 in terms of the scattering efficiency, $Q = \sigma/\pi r^2$. This figure demonstrates that for small spheres with $mx \ll 1$, ($x = 2\pi n_0 r/\lambda$ and $m = n/n_0 = 1.59/1.33$), the scattering efficiencies of Rayleigh and Mie scattering are very nearly the same, whereas for larger spheres with high mx values, the behavior is completely different. The Mie scattering efficiency departs from the Rayleigh λ^{-4} behavior and approaches a limiting value of $Q = 2$, as a consequence of the “extinction paradox” related to equal

geometrical and diffraction contributions to the cross section [10]. The diffraction contribution is most readily discerned at a distance from the sphere and is strongly peaked in the forward direction. Thus, Mie scattering produces a scattering pattern like an antenna lobe with a forward lobe that becomes more intense and sharper with increasing particle size. For larger particle sizes, as Fig. 6 shows, Mie scattering is not strongly wavelength dependent. This is the reason that such scattering from water droplets in clouds, mist, or fog produces white light, as can be seen in Fig. 4 in the lower part of the sky behind the lion. Likewise, due to its larger forward lobe, Mie scattering produces the whitish glare that is seen surrounding the sun when large particulate matter is present in the air.

Quantum Description

In describing Rayleigh scattering, only the classical interaction of light with small particles has been considered so far. However, for very small particles, a proper account of Rayleigh scattering requires a quantum-mechanical description. This is given, for example, by Placzek [14] in the early days of quantum theory and, in a more modern setting, by Loudon [15], which is followed here. The scattering of light by an atom or molecule is a second-order radiative process: a quantum (or photon) of energy

Rayleigh and Mie Scattering,

Fig. 6 Scattering efficiency $Q = \sigma/\pi r^2$ versus mx ($x = 2\pi n_0 r/\lambda$ and $m = n/n_0 = 1.59/1.33$) for Rayleigh (*dashed curve*) and Mie (*solid curve*) scattering. The dotted line indicates the limiting value of $Q = 2$. (Reproduced with permission from A.J. Cox, A.J. DeWeerd and J. Linden, Am. J. Phys. 70, 620–625 (2002). Rayleigh and Mie Scattering,

Fig. 7 Quantum energy level transition representation of (1) Raman Stokes scattering, (2) Rayleigh scattering, and (3) Raman anti-Stokes scattering. The corresponding peaks created in the light scattering spectrum are shown below the three sets of different virtual transitions. (After David J. Lockwood, Ph.D. Thesis, Canterbury University, 1969)

$\hbar\omega$ (ω is the angular frequency and $\hbar = h/2\pi$, where h is Planck's constant) of the incident light beam is destroyed and a quantum of scattered light of energy $\hbar\omega_s$ is created. When $\omega_s = \omega$, the process is called elastic scattering or Rayleigh scattering in the nomenclature of this field of research, which is where the use of terminology leads to naming confusions for different scattering processes [7]. When $\omega_s \neq \omega$, the process is called inelastic scattering or Raman scattering; the energy difference thus created is accommodated by the atom or molecule that is involved in the scattering process. Energy may be transferred to, or taken from, the atom or molecule via an electronic transition, in which case it is called Raman Stokes or Raman anti-Stokes scattering. These three different electronic energy transition processes are illustrated in Fig. 7. Electronic

transitions can occur between any states but usually arise from or terminate at the ground state or thermally populated higher states, and the excited states are usually virtual states, that is, they are not stationary states of the system. However, if the energy of the incident or scattered light is close to or at a stationary energy state, electronic resonant scattering occurs.

After a full quantum-mechanical derivation, the differential cross section of the elastic scattering of light by an atom, $d\sigma/d\Omega$, can be written as [15]

$$d\sigma/d\Omega = \left(\frac{e^4 \omega^4}{16\pi^2 \epsilon_0^2 \hbar^2 c^4} \right) \left| \sum \{ [\mathbf{e}_s \cdot \mathbf{D}_{li} \mathbf{e}_i \cdot \mathbf{D}_{il} / (\omega_i - \omega)] + [\mathbf{e}_i \cdot \mathbf{D}_{li} \mathbf{e}_s \cdot \mathbf{D}_{il} / (\omega_i + \omega)] \} \right|^2, \quad (5)$$

for the case of the atom returning to its ground state $i = 1$ at the conclusion of the scattering event. The summation index i runs over all the eigenstates of the atomic Hamiltonian. Note that the cross section varies as the fourth power of the frequency of the incident light, as in the classical result. This equation is a simplified form of the general Kramers-Heisenberg formula for the differential cross section that also covers inelastic Raman scattering [15] and forms the basis for quantum-mechanical scattering theory. In Eq. 5, the summation is carried out over all stationary states i ; c is the velocity of light, e is the electron charge, $\mathbf{\epsilon}$ and $\mathbf{\epsilon}_s$ are the unit polarization vectors for the incident and scattered light, and $\mathbf{D}$ is the sum of the electron coordinates and is proportional to the atomic-dipole moment. Evaluating the matrix elements that determine $\mathbf{D}$ is not trivial and has only been performed for simple systems such as atomic hydrogen [16].

Equation 5 may be simplified under two limiting conditions. The first is where ω is much larger than an atomic excitation frequency ω_i , but much less than $mc^2/\hbar$ where m is the electron mass. In this high-frequency limit (corresponding to Thomson scattering), the cross section reduces simply to [15].

$$d\sigma/d\Omega = Z^2 r_e^2 (\mathbf{\epsilon} \cdot \mathbf{\epsilon}_s)^2 (\text{for } \omega \gg \omega_i) \quad (6)$$

where Z is the number of electrons in the atom and $r_e = e^2/4\pi\epsilon_0 mc^2$ is the classical electron radius. Interestingly, this result from the quantum theory for the elastic scattering cross section in the high-frequency limit is identical to that obtained from the classical theory for Thomson scattering [15].

The second limiting case is where ω is much smaller than all atomic excitation frequencies ω_i , in which case Eq. 5 becomes [15]

$$d\sigma/d\Omega = (e^4 \omega^4 / 16\pi^2 \epsilon_0^2 \hbar^2 c^4) \left| \sum (\mathbf{\epsilon}_s \cdot \mathbf{D}_{1i} \mathbf{\epsilon} \cdot \mathbf{D}_{i1} + \mathbf{\epsilon} \cdot \mathbf{D}_{1i} \mathbf{\epsilon}_s \cdot \mathbf{D}_{i1}) / \omega_i \right|^2. \quad (7)$$

This expression for the cross section in the low-frequency limit can readily be evaluated for atomic hydrogen, yielding [15, 16]

$$d\sigma/d\Omega = (81 r_e^2 / 64) \times (\omega/\omega_R)^4 (\mathbf{\epsilon} \cdot \mathbf{\epsilon}_s)^2 \quad (\text{for } \omega \ll \omega_i), \quad (8)$$

where $\hbar\omega_R = me^4/32\pi^2\epsilon_0^2\hbar^2$ is the ground-state binding energy of hydrogen.

The full expression given in Eq. 5 for the elastic scattering cross section has been determined for hydrogen by Gavrilu [16]. His tables of results for the magnitude of the scattering matrix element as a function of the frequency of the incident light have been graphically depicted by Loudon [15], and some results are illustrated in Fig. 8. For this case, the differential cross section can be written as [15].

$$d\sigma/d\Omega = r_e^2 |M_1|^2 (\mathbf{\epsilon} \cdot \mathbf{\epsilon}_s)^2, \quad (9)$$

where

$$M_1 = (m\omega^2/\hbar) \sum (2\omega_i |X_{1i}|^2) / (\omega_i^2 - \omega^2) \quad (10)$$

and X_{1i} are the appropriate electric-dipole matrix elements. Note that in the frequency region below ω_R , there are several strong electronic transition resonances evident (only those up to the fifth excited state were calculated by Gavrilu), separated by zeros in the differential cross section. Such resonances could not be predicted from the classical model used by Rayleigh. The inclusion of radiative damping in the theory removes the infinite values from the cross section and the accompanying zeroes evident in Fig. 8. Note also that at high frequencies, the cross-sectional value approaches that of Thomson scattering, as given by Eq. 6 with $Z = 1$, and eventually reaches it when $\omega \gg \omega_i$.

Representative Scattering Media

Here, we review Rayleigh and Mie scattering processes at work in different media of interest, including solids, liquids, and gases. Some examples of practical applications of Rayleigh and Mie

Rayleigh and Mie Scattering,

Fig. 8 Frequency dependence of the elastic scattering matrix element $|M_1|^2$ for a hydrogen atom. The vertical dashed lines show the positions of resonances with $n = 2, 3, 4$, and 5 electronic excited states. The horizontal dashed line shows the limiting value of $|M_1|^2$ for $\omega \gg \omega_R$ in the Thomson scattering region. (From Ref. [15] after the work of M. Gavrilu [16]):

Rayleigh and Mie Scattering, Fig. 9

scattering in these representative media are also provided.

In fluids, conventional Rayleigh scattering is most commonly observed. Although proof of Rayleigh's law in gases was obtained quite early on [2, 17], at just a few isolated wavelengths, it was not until later that similar information was obtained over a wide wavelength range. In 1973,

Stone [18] reported on measurements of the Rayleigh scattering from CCl_4 and C_2Cl_4 as a function of wavelength between 600 and 1060 nm by placing the liquid sample in a hollow fused-quartz fiber and measuring the light scattered by the liquid through the fiber wall. Stone determined that the scattering loss rate was 25 dB/km for CCl_4 and 68 dB/km for C_2Cl_4 at 632.8 nm and

that the scattering loss rate followed a λ^{-4} dependence over the entire spectral range.

As mentioned in the Introduction, Rayleigh scattering is most commonly encountered in nature with the spectacular variations in color of the sky during the day and at sunset. In the absence of these scattering effects from atmospheric gases, the sky would be black, just like in outer space (Fig. 9). In practical applications, Rayleigh scattering from gaseous molecules is becoming an increasingly useful tool for diagnostic purposes. For example, Rayleigh imaging is particularly advantageous for visualizing the complex flow fields in fluid dynamics and combustion phenomena associated with shock waves and boundary layer structures having large density fluctuations [19]. In these measurements, quantitative information on these complex structures is generated by using high-power short-pulse lasers that freeze the density field in time.

In solids, there are many examples of Rayleigh scattering at work. For example, Rayleigh scattering is mainly responsible for the blue appearance of opalescent materials when viewed under white light (Fig. 10), although photonic band gap effects related to their microscopic structure frequently introduce striking color variations in their appearance, as can be seen in Fig. 10. The transmission

Rayleigh and Mie Scattering, Fig. 10 Rayleigh scattering of white light from an Australian opal. (Copyright David J. Lockwood)

of optical signals in optical fibers [20] and within microspheres or microdisks [21] is strongly affected by optical scattering processes including significant Rayleigh scattering. Glass fibers are disordered materials that exhibit microscopic variations in their density and refractive index. Rayleigh scattering from these fluctuations results in unwanted energy losses in optical transmission through the fiber with an attenuation coefficient, α_R , given by [20, 21]

$$\alpha_R = (8\pi^3/3\lambda^4)n^8p^2kT\beta_T \quad (11)$$

where n is the fiber refractive index, p is the photoelastic coefficient of the glass, k is the Boltzmann constant, β_T is the isothermal compressibility, and T is a fictitious temperature at which the density fluctuations are “frozen” into the glass (~ 1500 K for fused silica). Note that as the contribution of Rayleigh scattering to the attenuation coefficient scales with the inverse fourth power of the wavelength, the Rayleigh scattering losses predominate at shorter wavelengths. A more unusual example is the observation of recoilless Rayleigh scattering by atoms in solids. This has been observed, for example, by employing equipment designed for Mossbauer effect studies (i.e., photon sources and analyzers with extreme selectivity in energy) to observe Rayleigh scattering in Pt, Al, graphite, and paraffin using an incident light energy of 23.8 keV [22].

Unusual Rayleigh scattering effects can also be seen in solids. For example, optical studies of gases contained in nanoporous materials with 70-nm-diameter pores show a λ^{-4} Rayleigh-type decay of the scattering coefficient with increasing wavelength [23]. Measurements of light scattering spectra from rutile structure fluorides using circularly polarized incident light have revealed Rayleigh optical activity. This occurs when the incident light is tilted away from the crystal c -axis direction of the tetragonal crystal structure [24]. Rayleigh optical activity is observed experimentally through a difference in the intensity of the Rayleigh scattering when excited with right and left circularly polarized incident light. The

Rayleigh and Mie

Scattering, Fig. 11 CID spectrum of the Rayleigh scattering in MgF_2 with the crystal rotated by angle θ_e around the laboratory y -axis (crystal a -axis). The crystal c -axis is in near alignment with the laboratory z -axis. (After Ref. [24])

Rayleigh circular intensity differential (CID), Δ_α , is defined by

$$\Delta_\alpha = (I_\alpha^R - I_\alpha^L) / (I_\alpha^R + I_\alpha^L) \quad (12)$$

where I_α^R and I_α^L are the scattered light intensities with α polarization due to right and left circularly polarized incident light, respectively. The dependence of the CID spectrum on small rotations of the crystal about the laboratory y -axis was measured in optically transparent MgF_2 and in crown glass for reference purposes. For the case of the crystal $c(a)$ axis nearly aligned along the direction of the monochromatic incident (scattered) laser light, the strong dependence of the Rayleigh CID spectrum on the crystal angle is shown in Fig. 11. Most importantly for correct identification purposes, the CID changes sign as the crystal is rotated through the true c -axis alignment at $\theta_e = -0.7^\circ$. Notably, no CID is observed for small rotations of the crystal about the orientation where the incident light and scattered light propagate perpendicular to the optic (c) axis, nor is any CID observed from the crown glass. These results indicate that the Rayleigh scattering CID observed in the MgF_2 crystal is due to depolarization effects associated with its birefringence and not polarization-dependent scattering cross sections, as confirmed theoretically [24].

Mie scattering is also found everywhere in nature: in the lower atmosphere, as noted above, in fluids like milk and latex paint, and even in biological tissue. In the latter case, Mie theory has been applied to determine if scattered light from appropriately treated tissue can be used to diagnose cancerous from healthy cells [25, 26]. Mie scattering is used in particle size determination for particles in non-absorbing media [27–29], in the determination of the oil concentration in polluted water [30], in parasitology [31], and in the design of metamaterials [32].

There has been a renewed interest recently in Mie scattering, and to a lesser extent Rayleigh scattering, for applications involving the optical properties of nanoparticles (spheres or dots) and special nanostructures such as nanorods or nanodisks. For example, the theory of Mie scattering has been extended to include the special optical properties of specific types of nanoparticles. Modeling of a Fano resonance [33] – resonances that occur in optics when a discrete localized state becomes coupled to a continuum of states – in Mie scattering from a high-index dielectric nanorod has shown that the scattering may be switched from total reflection to total transmission [34]. Remarkably, this feature means that under appropriate conditions, an incident transverse-electric-polarized light beam passes through the nanorod with practically no scattering, and the

nanorod becomes invisible for any angle of observation.

On the other hand, Mie resonances can also play a central role in presenting novel ways for boosting many optical effects near magnetic and electric multipolar resonances, as well as driving a variety of interference phenomena that govern recently discovered novel effects in meta-optics and nanophotonics [35]. Such resonances accompany the scattering of electromagnetic waves by subwavelength objects and can modify markedly the scattered light intensity and radiation pattern. Other areas of newer research related to Mie scattering include modifications of Mie theory for dielectric nanoparticles to include the toroidal dipole moment [36] as well as the usual electric-dipole moment that yields a nonradiating source (anapole) mode, which has been observed experimentally for a Si nanodisk [37], and Mie scattering color quantification has been applied in smartphone-based monitoring of microbial contamination on food products [38].

Whispering gallery mode resonators take advantage of strong light confinement and a long photon lifetime for applications in quantum optics, optomechanics, microlasers, and sensing. Cavity-enhanced Rayleigh scattering from nanoscatterers placed on the resonator surface has been shown to strongly enhance the free-space coupling of light into, and out from, the resonator [39]. Resonance Rayleigh scattering, typically involving plasmons in gold nanoparticles [40], is being applied widely to investigate biological materials such as cancer cells, food contaminants, and various metal ions (see, e.g., References [41–45]).

In summary, it is evident that Rayleigh scattering and Mie scattering are ubiquitous, being found in the everyday and colorful optical wonders that surround us.

Reflectance Standards

Bor-Jiunn Wen¹ and Chao-Hua Wen²

¹Department of Mechanical and Mechatronic Engineering, National Taiwan Ocean University, Keelung, Taiwan

²Center for Measurement Standards, Industrial Technology Research Institute, Hsinchu, Taiwan

Definition

A reflectance standard is a physical reference sample including ratio values between the total amount of radiation, as of light, reflected by a surface and the total amount of radiation incident on the surface across visible spectrum. Reflectance standards are used for calibration and verification of spectrometers. There are two kinds of reflectance standards: diffuse and specular. In practice, both white and black reflectance standards are utilized for calibration. They require a similar specular or diffuse surface property to the device under test (DUT).

Applications

Diffuse and specular reflectance standards are used to calibrate colorimeters, reflectometers, spectroradiometers, bidirectional reflectance distribution function (BRDF) scatterometers [1], ultraviolet-visible (UV-VIS) spectrophotometers, and Fourier transform infrared spectroscopy (FTIR) spectrometers.

Diffuse white reflectance standard samples can be obtained with diffuse reflectance of 98% or more. Some materials can be carefully sanded (some require water with the sanding) or cleaned to refresh the surface backup to its maximum reflectance as the surface becomes soiled or contaminated. Such reflectance standards can be used for making illuminance from a luminance measurement of the standard. Moreover, with the proper measurement geometry, luminance factor

can also be obtained. Therefore, the specified measurement geometry is used to calibrate the standard. If the reflectance (or diffuse reflectance) of the standard is around 98% or 99%, it usually does refer to the reflectance, and then that value can only be used for a uniform hemispherical illumination. For industrial applications, white ceramic tiles are often used for a reflectance of 90%. If we use an isolated source at some angle, there is no reason to expect that the 99% value is even close to the proper value of the luminance factor for that geometrical configuration [1–3].

For calibration of the spectral reflection, the reference white standard and the reference black standard with the calibrated spectral reflectance factor $R_{WS}(\lambda)$ and $R_{BS}(\lambda)$, respectively, are used under the same measurement geometry [4]. Figure 1 depicts white and black specular reflectance standards, respectively. In many commercial measurement instruments, black wedges are popular as the black specular reflectance standards of optical measurements.

In order to measure the spectral reflection of the device under test (DUT), set up the measurement geometry and warm up the light source. First, measure the spectral reflectance factors of the reference white standard, $R_{WS}'(\lambda)$, with a spectrophotometer. Second, measure the spectral reflectance factors of the reference black standard, $R_{BS}'(\lambda)$. Third, measure the spectral reflectance factor of DUT, $R'(\lambda)$. The spectral reflectance factor, $R(\lambda)$, is calculated in Eq. (1):

$$R(\lambda) = [R'(\lambda) - R_{BS}'(\lambda)] \cdot \left[\frac{R_{WS}(\lambda) - R_{BS}(\lambda)}{R_{WS}'(\lambda) - R_{BS}'(\lambda)} \right] + R_{BS}(\lambda) \quad (1)$$

where $R_{WS}(\lambda)$ and $R_{BS}(\lambda)$ are the calibrated spectral reflectance factors of the reference white standard and the reference black standard, respectively. Then, the International Commission on Illumination's (CIE) tristimulus values, X , Y , and Z , are obtained as:

Reflectance Standards, Fig. 1 (a) White and (b) black specular reflectance standards

$$\begin{cases} X = k \cdot \sum_{\lambda} R(\lambda) \cdot S(\lambda) \cdot \bar{x}(\lambda) \cdot \Delta\lambda \\ Y = k \cdot \sum_{\lambda} R(\lambda) \cdot S(\lambda) \cdot \bar{y}(\lambda) \cdot \Delta\lambda \\ Z = k \cdot \sum_{\lambda} R(\lambda) \cdot S(\lambda) \cdot \bar{z}(\lambda) \cdot \Delta\lambda \end{cases} \quad (2)$$

where

$$k = \frac{100}{\sum_{\lambda} S(\lambda) \cdot \bar{y}(\lambda) \cdot \Delta\lambda}$$

$S(\lambda)$: the relative spectral power distribution of the illuminant considered

$\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$: color matching functions of CIE 1931 standard colorimetric observer

$R(\lambda)$: spectral reflectance factor of the DUT

$\Delta\lambda$: wavelength interval in nm

λ : wavelength range from 380 to 780 nm

For the calibration of the filtered photometric reflection, the reference white standard and the reference black standard of calibrated CIE tristimulus values (X_{WS} , Y_{WS} , Z_{WS}) and (X_{BS} , Y_{BS} , Z_{BS}), respectively, for the same measurement geometry as in the test configuration shall be used [4]. The measuring procedures of the filtered photometric reflection of DUT are described as follows.

First, set up the measurement geometry and warm up the light source. Second, measure the CIE tristimulus values of the reference white standard, X_{WS}' , Y_{WS}' , and Z_{WS}' , with a colorimeter. Third, measure the CIE tristimulus values of the reference black standard, X_{BS}' , Y_{BS}' , and Z_{BS}' . Finally, measure the CIE tristimulus values of DUT, X' , Y' , and Z' . CIE tristimulus values of the filtered photometric reflection of DUT, X , Y , and Z , are obtained using Eq. (3):

$$\begin{cases} X = [X' - X_{BS}'] \left[\frac{X_{WS} - X_{BS}}{X_{WS}' - X_{BS}'} \right] + X_{BS} \\ Y = [Y' - Y_{BS}'] \left[\frac{Y_{WS} - Y_{BS}}{Y_{WS}' - Y_{BS}'} \right] + Y_{BS} \\ Z = [Z' - Z_{BS}'] \left[\frac{Z_{WS} - Z_{BS}}{Z_{WS}' - Z_{BS}'} \right] + Z_{BS} \end{cases} \quad (3)$$

where X_{WS} , Y_{WS} , and Z_{WS} and X_{BS} , Y_{BS} , and Z_{BS} are the calibrated CIE tristimulus values of the reference white standard and the reference black standard, respectively.

The measurement method of the spectral or the filtered photometric reflection is utilized for the reflection of DUT by using a spectrophotometer or a colorimeter. Compared to the filtered photometric reflection, results of the spectral reflection

measurement include wavelength information. However, a spectrophotometer is more expensive than a colorimeter. According to practical applications, the measurement method of the spectral or the filtered photometric reflection is appropriately utilized. Typically, color, fluorescence, grayscale, and wavelength reflectance standards are usually used in the color industry. They are used to check the reliability of operating the instruments. Various types of standards depending on different kinds of applications are introduced as following sections.

Color Reflectance Standards

Diffuse color standards are used to calibrate colorimeters and spectrophotometers in the 360–830 nm range. Compared with standards for gloss surfaces, the diffuse essential standards simplify measurements by removing the effects of viewing or illumination geometries.

Fluorescence Reflectance Standards

Fluorescence standards aid in the development of optically brightened materials such as paper and textiles and are widely used in the cosmetic industry as well. The appearance of an illuminated object is dependent upon the illumination and viewing conditions. For example, the total radiance factor of paper and board product containing fluorescent whitening agents (FWAs) is the sum of the reflected radiance factor and the luminescent radiance factor [5]. The magnitude of the luminescent radiance factor depends on the amount of UV radiation of the illumination and the fluorescence of the FWAs. It is therefore essential to calibrate not only the radiance (reflectance) factor scale but also the UV content of the illumination used in the measurement apparatus. The adjustment for the UV content is achieved by adjusting the position of the adjustable UV filter in the apparatus so that the light incident upon the sample has an effective UV content corresponding to that in the CIE illuminant C. The UV filter adjustment is based on the ISO brightness ($C/2^\circ$) value [5].

Grayscale Reflectance Standards

Grayscale diffuse reflectance standards are used to establish the linearity and accuracy of reflectance spectrophotometers and colorimeters. The standards are suitable for users who need a wide dynamic range of reflectance values that are abbreviated in range, but not in number of calibration steps. The industries typically require such a range, such as clay and processed minerals, paper, and paints, which accurately reproduces the range of reflectance values exhibited by those products.

Wavelength Reflectance Standards

Wavelength calibration standards provide stable absorption spectra for validating the wavelength calibration of spectrophotometers in the ultraviolet-visible-near-infrared (UV-VIS-NIR) region. Complete absorption spectral data are supplied with each standard. The three standards available are holmium oxide standard for the UV-VIS-NIR calibrations, dysprosium oxide standard for NIR calibrations, and erbium oxide standard for VIS-NIR calibrations. Alternatively, a mixed oxide standard is available that is doped with all three rare-earth oxides for use over the entire UV-VIS-NIR region.

[Simulation and image synthesis of natural phenomena](#)

Definition

In computer graphics, rendering is a process of synthetically generating an image – or a sequence of images – of an object, based on its mathematical and possibly physical description. Natural phenomena are inherently very diverse, and therefore, their rendering is a very heterogeneous field with different paradigms and approaches.

As the name implies the objects and phenomena of interest will mainly have a natural origin. However, due to similar characteristics of the underlying problems, rendering of artificial objects made of natural materials is often considered a part of the field as well.

Although the main target of rendering is the creation of images, it is usually not trivial to obtain the mathematical and physical description of the simulated entities (i.e., the input data). Because of this the rendering algorithms can potentially require coupling with simulation

methods, which provide means to computationally generate the required data. Alternatively, acquired or even hand-modeled data can be used, in case the simulation proves to be infeasible for some reason (e.g., too time-consuming).

Categories of Natural Phenomena

The richness of the natural environment of course implies the existence of a tremendous amount of phenomena and objects. The structure of this system is hardly apparent, but can roughly be classified according to the physical characteristics of the phenomena as follows (also see examples in Fig. 1):

- **Sparse phenomena**, involving gases, aerosols, and vapors but also effects of electromagnetism or high-energy particles. These include various well-known meteorological phenomena like atmospheric scattering, clouds, fog, rainbows, or lightning; astronomical phenomena such as auroras, stars, nebulae, and other stellar bodies; and also smaller-scale phenomena like fire, smoke, and dust.
- **Fluid phenomena**, most notably oceans and other large water bodies and effects associated with their surfaces, such as waves and streams. Also medium- and small-scale liquid substances, especially beverages like milk, fruit juices, and coffee; suspensions like blood, paints, and inks; and volcanic phenomena such as lava flow. In addition, especially from the perspective of simulation methodology, it is possible to regard fine-grained solid materials like sand and partly solid substances such as gels, as fluid phenomena.
- **Solid objects and phenomena**. On a large scale, primarily geological formations ranging from mountains to entire planets. On a medium scale, organic entities like vegetation, biological tissues, hair, and fur and inorganic objects such as ice and rock formations, crystals, metals and their alloys, and man-made objects manufactured from these. Among small-scale solid objects, most effort has been focused on rendering precious gems. Additionally,

Rendering Natural Phenomena, Fig. 1 Examples of sparse, fluid, and solid phenomena

rendering of natural and artificial solid objects exhibiting a layered structure has attracted research attention, for example, coated or painted objects, oxidized and patinated metals, composite materials, gemstones, and many others.

From the perspective of rendering and also modeling, another important distinction can be made between phenomena and objects with well-definable geometry and opaque surfaces and those with a dominating volumetric character (either from the spatial or the optical point of view).

The first group will likely be modeled using geometric primitives and rendered with algorithms suitable for distinguishing between discrete parts of the phenomenon, e.g., the object-air interface. The light interaction will primarily be taking place on these interfaces, mainly

as reflection and refraction. Most opaque solids belong into this category but also some fluid substances, such as clear liquids.

On the other hand, the second group will likely utilize a volumetric representation (or a combination with a geometric one) and naturally also volume-rendering methods. Materials with these properties are called participating media, and the dominating optical interactions here will be scattering and absorption. These characteristics are inherent to virtually all sparse phenomena but also to most fluid and many solid ones.

This distinction is naturally relative and without a sharp transition. As an example, one can imagine that a small stone grain will be translucent and have an apparent volumetric structure, while a large piece will appear opaque and will interact with light mostly by diffuse surface reflection (Fig. 2).

Rendering Natural Phenomena, Fig. 2 A small quartz crystal and a large piece of sandstone

Causes of Color

Another important aspect of natural phenomena from the perspective of color science is how they interact with light and produce color and the overall appearance [1]:

- **Emission**, due to *incandescence* (e.g., stellar radiation, volcanic activity, lightning), *gas excitation* (auroras, artificial gas lamps), or a combination of these (fire). The variation of color is primarily caused by varying energy density. Virtually all natural light originates in these processes.
- **Geometric causes**, such as *scattering* (atmosphere, clouds, smoke, milk, and generally almost all substances exhibiting volumetric properties or diffuse reflection), *dispersion* (rainbows, sundogs, snow), *diffraction* (opals, thin filament-like objects such as spider webs and hair, carapaces of certain bugs), *interference* (single- or multilayered structures such as bubbles and certain gemstones and insects), and *polarization* (specular reflection from smooth surfaces). These interactions are usually elastic, i.e., they conserve energy, and the color variation is mainly caused by geometric configurations and relations.
- **Absorption and reemission**, mostly in *organic compounds* (plant and animal tissues, natural and artificial pigments, dyes, and inks)

and all *metals* but also in certain minerals and semiconductors and occasionally in light liquids, most notably in *pure water*. These interactions are usually inelastic, leading to energy loss described by the Beer-Bouguer law. Color variation is caused by relative efficiency of the reemission in different wavelengths.

Historical Overview

Synthesizing physically plausible images of natural phenomena has arguably been one of the primary foci of rendering from the beginning [2]. However, the complexity of most natural phenomena prevented their plausible rendering until the early 1980s, mostly because of the lack of theoretical understanding and computational power.

A significant milestone was reached by introducing radiosity [3] and stochastic ray tracing [4] algorithms in 1984, enabling physically based simulation of global illumination effects. A more general solution was then presented in 1986 [5] by James Kajiya in the form of the rendering equation – a unified mathematical framework that enables the simulation of all effects that conform to geometric optics. These approaches were then extended to rendering of volumetric phenomena in the late 1980s and early 1990s.

Algorithmic improvements have gone hand in hand with the evolution of computing hardware,

making rendering of image sequences and even entire movies feasible by the end of the 1980s. However, probably the biggest breakthrough came with the introduction of parallel programmable graphics processor units (GPUs) to the consumer market in 2001. Their programmability enables researchers and developers to produce specialized algorithms focused on simulating and rendering effects of diverse nature. Programmable GPUs quickly became widespread and enabled the development of algorithms and applications capable of simulating numerous natural phenomena, including video games and other interactive applications.

Rendering Methodologies

The traditional view is to split (realistic) rendering as a field into noninteractive (“offline”) rendering [2] and interactive rendering [6], with the former putting emphasis on quality and the latter on speed. This applies to rendering of natural phenomena just as well. The spectrum of possible approaches is however much more continuous than that and rather depends on the *paradigm* chosen for designing a particular rendering method (refer to Figs. 3 and 4).

Empirical or phenomenological methods are generally *top-down*; their design starts by collecting observations of a phenomenon to be simulated and then proceeds to invent an arbitrary algorithm which best reproduces the phenomenon while keeping computational costs as low as possible. As such, empirical methods are used mainly in interactive applications where the important factors are visual plausibility, robustness, and speed, while physical plausibility and radiometric accuracy are secondary. Notable examples include:

- **The Lambert reflectance model** (1760) states that reflection from a sufficiently rough surface is perfectly diffuse, i.e., isotropic with regard to observation direction. Despite building on physically meaningful assumptions (multiple scattering underneath the surface) and the fact that many materials (such as uncoated paper)

behave very closely to the model, there is no ideal diffuse reflector.

- **The Phong reflectance model** (1975) approximates reflection from glossy surfaces by the cosine function raised to an exponent proportional to the surface smoothness. This leads to reflection in the form of a blurry circular patch which gets brighter and smaller with increasing smoothness and in the limit case corresponds to the Dirac function for a perfect mirror. Despite having no physical basis, the model has been widely adopted and is still used, mainly thanks to its simplicity.
- **Particle systems** (1983) are ubiquitously used in both interactive and offline applications to model volumetric phenomena (such as clouds). In this sense, particles are small semitransparent entities often modeled by mapping a texture onto a rectangular geometric primitive that always faces the observer. If used in sufficient numbers, they are able to mask their discrete nature, while still being cheaper than the corresponding full volumetric representation (e.g., a 3D voxel grid). However, simulating global illumination effects in conjunction with particle systems requires additional effort, which might hinder their utilization. As a result it is often necessary to design another empirical model to compute illumination in an intended way, increasing the necessary amount of work.

The main downsides of empirical methods are that they often require a lot of artistic supervision during the content creation process and that they seldom work outside the range of phenomena they were designed for.

Physically based methods proceed in the opposite, bottom-up fashion. Using physically meaningful data, these methods apply the laws of physics to render the target phenomenon. Consequently, rather than being centered around a particular simulated phenomenon, these methods share more principal similarities and are usually useful for rendering a whole class of phenomena to which the implemented laws and assumptions apply. On the downside, their computational cost is often much higher than that in empirical approaches. This is usually treated by applying

Rendering Natural Phenomena, Fig. 3 A comparison of interactive (empirical versus physically based) methods for rendering atmospheric scattering and clouds. The empirical approaches are typically faster, but produce less

dynamic and believable results and in some cases require additional artistic input (Image credit: Petr Kellnhofer using the model of Sean O’Neil, (*top ‘sunset’ pair*), Niniane Wang (*top ‘clouds’ pair*))

Rendering Natural Phenomena, Fig. 4 A comparison of empirical and physically based reflectance models. *Top row:* The Lambert and the (physically based) Oren-Nayar models on a diffuse gray clay material. The Oren-Nayar model correctly produces a “flatter” distribution, which is caused by backscattering on the rough clay surface. *Bottom row:* A glossy object made of gold, reflecting an environment map. The Torrance-Sparrow model

produces a more plausible reflection, which is mainly visible in grazing angles where the Phong model incorrectly produces darker reflections in disagreement with the Fresnel law. In addition, the Phong model fails to reproduce the yellow hue of gold, since it does not handle conductors properly. This could only be obtained by additional manual tweaking

Occam’s razor, simplifying the rendering algorithm in ways that decrease the simulation time but do not negatively affect the result. Examples of such methods include:

- **The Torrance-Sparrow reflectance model** (1992) simulates reflection from rough glossy surfaces (and as such being an alternative to the Phong model). The method considers the simulated surface to consist of microscopic facets oriented according to a certain statistical distribution (i.e., Gaussian distribution). Each facet is assumed to reflect light according to the Fresnel law, and additionally, probabilistic shadowing of neighboring facets is taken into account. Although in some situations the model produces results similar to the Phong model, it is energy conserving, correctly handles objects made of conductors, and behaves plausibly in grazing angles, albeit being somewhat more difficult to understand.

- **Photon mapping** (1996) [7] is a general framework for rendering global illumination effects. It is applicable to both surface and volume illumination, which makes it especially suitable for rendering natural phenomena. Its main idea lies in distributing the light energy by shooting and tracing small energy particles, photons. Every interaction of a photon with the simulated environment is recorded, and when all illumination energy is distributed, the algorithm calculates the energy density at observed locations by performing local photon density estimation. Much work has been invested into improving the original technique, resulting in one of the most versatile global illumination algorithms to date.

Originally, physically based methods were only used in offline applications. Recently, however, with the increasing performance and flexibility of the programmable hardware, the

boundary between offline and interactive methods has gotten weaker. Many physically based rendering algorithms (such as ray tracing or photon mapping) can today be implemented to run interactively, albeit with decreased rendering quality.

Finally, **predictive methods** represent a step further than physically based methods. Opposite to empirical approaches, their primary focus is physical correctness and radiometric accuracy. The utilized algorithms must be spectral, unbiased, and support all significant physical phenomena that occur in the simulated environment. They require measured and acquired input data, and the results usually need to be viewed under controlled conditions. The resulting methods typically need validation and are generally very slow, even compared to physically based approaches. As such they are useful mainly in virtual prototyping applications such as in automotive industry, architecture, and gem processing.

Phenomena Simulation

As mentioned in the “Introduction,” in addition to rendering a phenomenon (and thereby producing an image of its momentary appearance), it is often necessary to obtain data about its spatial and temporal development prior to the rendering. Virtually all natural phenomena are dynamic in a certain sense, and this dynamicity can be regarded in the short and the long term.

Short-term development usually stems from the character of the phenomenon itself and its internal dynamics. Its nature can be *synthetic* (e.g., condensation of water vapor leading to cloud formation), *evolutionary* (for instance, flow of liquid particles in a stream), or *destructive* (such as cracking or shattering of an iceberg). Capturing this behavior will often entail using discrete particle or continuous dynamics.

On the other hand, **long-term development** is usually related to interactions of a phenomenon with its surrounding environment [8], sometimes referred to as *weathering* (in case the process is destructive). Many forms of this behavior exist, for instance, terrain formation, soil erosion and

cracking, oxidation and patination of metals, organic tissue decomposition, and others.

From the methodological point of view, approaches for simulating natural phenomena can again be divided into empirical and physically based. Very often, however, a combination of these two shows to be the best compromise. The cause of this is arguably the fact that while it is often very difficult to devise an empirical method that captures the entire complexity of a given phenomenon well, a complete physically based simulation of any larger system can easily become intractable. Consequently, many approaches simulate the global behavior of the target phenomenon in a physical, possibly simplified way (for instance, using a reduced resolution of the simulated structure) and then add the remaining details empirically. The most frequent way to perform the latter is using *fractal* functions or systems:

- **Terrain rendering** methods usually generate the overall terrain morphology by simulating the orogenetic and erosive processes (or simply use satellite data) and add more detailed features by random fractal perturbations.
- **Rendering of plants** frequently employs the so-called L-systems to generate the plants and trees. L-systems are iterated functions described by grammars that imitate branching in real plants. Adding random perturbations into the system can produce plausibly looking plants with unlimited number of variants that retain the overall character defined by the L-system.
- **Rendering of ocean waves** can generate larger-scale waves with a fluid dynamics simulation or synthesizing them from trochoidal wave theory using measured wave frequency spectra and then again add random fractal perturbations to break disturbing repetitive patterns.

Despite the convenience of fractal functions, their inherent *iterative* nature makes them difficult to use in some cases. Therefore, efforts have been made to design regular functions with fractal properties. The most successful method to do so is the *Perlin noise* [9], which has become a

Rendering Natural Phenomena, Fig. 5 Multiple superposed frequencies (octaves) of Perlin noise (*top left*) and examples of procedurally generated content – terrain,

forest, and fire (Image credit: Franck Doassans (forest), Sergei Bolisov (fire))

cornerstone for generating many diverse natural phenomena and also fuelling future development in this area (see examples in Fig. 5). Since Perlin noise behaves as a regular function, it enables on-the-fly evaluation without requiring additional storage, making it feasible for use even in interactive applications.

It might of course be possible to acquire the data needed for rendering a given phenomenon, although in some cases this can prove difficult or impractical for quantitative reasons:

- The phenomenon of interest might be too large and as a result produce overwhelming amounts of data. A good example is acquisition of terrains, which, although today possible via satellite scanning, still does not produce data with resolution sufficient for some applications.
- Dynamic phenomena are generally difficult to acquire, especially in cases when the scanning process is slower than the rate of the phenomenon's significant change. Acquisition of flames and smoke is a good example here.
- Scanning processes yield limited amounts of instances of the target phenomenon. If many

such instances are needed (e.g., in cloud rendering), the cost of the acquisition process might become prohibitive.

Similar to physically, based simulation, however, these problems can in some cases be overcome by applying procedural perturbation techniques to the scanned data.

Future

The present knowledge in physics theoretically allows us to explain and hence simulate virtually all observable natural phenomena. The limiting factors in doing so are therefore always computational resources. In the future, the increasing memory density will enable us to work with larger natural systems, and the growing parallel computing power of CPUs and GPUs will allow simulation and rendering of more complex phenomena. Especially in interactive applications, the current trend of using physically based approaches over empirical ones will most likely continue.

Retinex Theory

John McCann

McCann Imaging, Arlington, MA, USA

Synonyms

[Color and lightness constancy](#); [Land Retinex theory](#)

Definition

Retinex is the theory of human color vision proposed by Edwin Land to account for color sensations in real scenes. Color constancy experiments showed that color does not correlate with receptor responses. In real scenes, the content of the entire image controls appearances. A triplet of L, M, S cone responses can appear any color. Land coined the word “Retinex” (the contraction of retina and cortex) to identify the spatial image processing responsible for color constancy. Further, he showed that color sensations are predicted by three apparent lightnesses observed in long-, middle-, and short-wave illumination. Retinex is also used as the name of computer algorithms that mimic vision’s spatial interactions to calculate the apparent lightnesses observed in complex scenes.

Overview

Edwin H. Land, the inventor of hundreds of photographic film patents, was struck by experiments showing that color sensations in real complex images depend on scene content. Film responds to the light falling on each tiny local region. Land realized that vision’s mechanisms were very different from film. His early experiments studied the colors observed in red and white projections [1]. He realized color appearance required both the cone responses to a local region and the neural spatial processing of the rest of the scene. He proposed the Retinex Theory.

Land coined the word Retinex to describe three independent spatial channels. In 1964, he wrote: “We would propose that all of the receptors with maximum sensitivity to the long-waves in the spectrum, for example, operate as a unit to form a complete record of long-wave stimuli from objects being observed. For convenience of reference, let us call this suggested retinal-cerebral system a ‘retinex’” [2–5]. It is the word that describes the mechanisms that perform the comparison of scene information to create the array of sensations of L, M, S lightness in each of human vision’s three channels.

Cone Quanta Catch

Visible light falls on objects that reflect some of it to the eye. Color vision depends on the spectrum of the illumination falling on an object and the spectrum of its reflectance. The product of these spectra describes the light coming to the eye. There are three types of cones in normal observers that are called L for long-wave-, M for middle-wave-, and S for short-wave-sensitive cones. The receptors’ spectral sensitivities multiplied by the light falling on the retina determine the L, M, S cone responses, namely, the “quanta catch” of the cones. The cones convert the quanta catch to

nerve signals that pass through many spatial comparisons in the visual system. The cone quanta catch is the important transition from the physics of light to the physiology of vision. However, it is just the first step in the process.

Figure 1 illustrates a laboratory experiment that generates equal L, M, S quanta catches from different reflectance papers.

At the top of Fig. 1, light passes through filters that determine the spectrum of each illumination falling on circular pieces of paper. The light coming to the eye from the papers is modified again by the reflectance spectra of the papers. Further, in this experiment, there is no light coming from the black surrounds.

On the left, there is a tungsten light source at the top. There is a filter that absorbs more middle-wave than long- and short-wave visible light (magenta arrows). The green circular paper reflects more middle-wave than long- and short-wave light. The light coming to the eye is the product of these spectra. The integrals of that light using the three cone spectral sensitivities determine the L, M, S quanta catch values.

On the right, there is the same tungsten light source at the top. There is a different filter that absorbs more long-wave than middle- and short-wave light (cyan arrows). The right-red paper reflects more long-wave than middle- and short-

Retinex Theory,

Fig. 1 Equal quanta catches from red and green papers. In a darkroom with a black surround, identical quanta catches appear the same – neither red nor green color appearances. When viewed alone, in a no-light background, the appearance of a spot of light correlates with cone quanta catch

wave light. In this experiment, the spectra of the two illuminants and the two reflectances were adjusted to generate the same triplet of LMS cone quanta catches. Under these conditions, the left-green paper and the right-red papers are identical retinal stimuli. They appear equal to each other, but that color is neither red nor green.

Mondrian Experiments

Land's color Mondrian experiment is similar, with the exception that he used a complex array of papers to simulate real-world scenes. The important difference is that in complex scenes, a particular quanta catch can appear any color: red, green, blue, yellow, white, or black.

Figure 2 shows the double color Mondrian experiment [6]. It used two identical Mondrians made of color papers, and two identical sets of illuminators. Each set had three different, non-overlapping spectral illuminants (long-, middle-, and short-wave visible light). Each projector

provided spatially uniform illumination for one spectral band, for one of the Mondrians. The amount of illumination from each projector was independently adjusted.

In this experiment, observers reported the colors of papers in the Mondrians. In this illustration, we will look at the circular red and green papers. Land adjusted the illuminant mixtures of light from the two sets of three projectors in order to control the light coming from the green and red papers. The same amounts of L, M, S light came from the green circle on the left as from the red circle on the right. First, he turned on just the long-wave lights. He adjusted the amounts of spatially uniform illumination falling on each Mondrian separately. He set the illumination so that the left-green circle and right-red circle had equal light-meter readings. Then, he did the same for middle- and short-wave light. The left-green and right-red circles had equal quanta catches by the L, M, S cones.

In this complex scene, observers reported that equal quanta catches circles appeared green on the

Retinex Theory, Fig. 2 Land's double Mondrian experiment. Two identical sets of matte colored papers, with separate L, M, S illuminating projectors with voltage transformers for control of the amount of spatially uniform light falling on each Mondrian. Telephotometer readings were projected above the Mondrians. Land separately measured

the L, M, S radiances from a green circle in the left Mondrian. Then, he adjusted the L, M, S radiances from a red circle on the right Mondrian to be the same. Observers reported different red and green colors produced by identical light stimuli

left and red on the right. Observers reported color constancy, namely, the red paper looked red and the green paper looked green despite the identical cone quanta catches.

Land repeated this experiment with all the Mondrian papers. A constant L, M, S quanta catch could generate any color sensation. The presence of the complex scene introduced more information to the visual system. The red and green papers appeared equal in Fig. 1: neither red, nor green. The red paper looked red and the green paper looked green in Fig. 2. The scene's spatial content stimulated vision's spatial image processing mechanisms to generate color constancy. The postreceptor visual processing plays a dominant role in color appearance in real scenes. Land's word "Retinex" gave this spatial process a name. He proposed a theoretical mechanism as well.

Retinex Mechanism

Figure 3 illustrates the pair of Mondrians in only long-wave light with more illumination on the left Mondrian, than on the right. The appearances of the two Mondrians are nearly constant. This is a common observation: Humans are insensitive to large changes in uniform illumination.

Retinex Theory,

Fig. 3 Pair of Mondrians in only long-wave light. Each rectangle in the left Mondrian has the identical reflectance as the corresponding rectangle in the right Mondrian. Only the circles have different reflectances. The left Mondrian has more illumination than the right. Observers report that the left Mondrian rectangles appear slightly lighter than the right rectangles. Each corresponding rectangle is nearly the same lightness in the left and right Mondrians

As illustrated here, in long-wave illumination, the left-green paper circle appeared dark when it generated the same L cone quanta catch as the lighter right-red circle. Vision's spatial image processing rendered the red and green papers with different apparent lightnesses in long-wave light. The lightnesses are stable with large changes in overall illumination.

Figure 4 illustrates the Mondrian viewed in middle-wave illumination. The left-green circle now appeared light, and the right-red circle looked dark. In Fig. 4, the circles had the same M cone quanta catch. Vision's spatial image processing rendered the red and green papers with different, and opposite, lightnesses in Fig. 3 and Fig. 4.

The left-green circular paper has more long-wave and less middle-wave illumination. The right-red circular paper has less long-wave and more middle-wave illumination. When adjusted using the telephotometer, those illuminations make the red and green papers to have identical radiances. Using the same procedure, Land adjusted the short-wave illuminants to make the left and right circles to have equal radiances. Having set the L, M, S illuminations so that both circles have equal radiances, Land turned on all six projectors. Although both circles caused identical cone quanta catches, observers reported that they had very different color appearances: red and

Retinex Theory,

Fig. 4 Pair of Mondrians in only middle-wave light. Now, the left Mondrian has less illumination than the right. In this waveband, the pattern of lightnesses differs from that in long-wave light. Observers report that the right Mondrian rectangles are slightly lighter than the left ones. Each corresponding rectangle is nearly the same lightness in the left and right Mondrians

green (illustrated in Fig. 2). Using this procedure, Land showed that a particular L, M, S quanta catch can appear any color.

James Clerk Maxwell invented colorimetry based on color matches. Also, he invented color photography based on three-color-separations with silver halide photographs. Both colorimetry matches and silver halide photography are molecular quanta catch events. It is easy to think that human vision uses those same mechanisms. But, color constancy disproves that hypothesis. Edwin Land's Retinex invention adopted the cone quanta catch as vision's initial receptor response but realized that vision's color appearance separations are the result of neural spatial comparisons, not receptors' cone quanta catch. Spatial comparisons are the basis of color constancy in complex scenes. Spatial comparisons form vision's L, M, S color separations.

These constancy observations led Land to propose the Retinex theory. The triplet of apparent lightnesses, not cone quanta catches, determines the color appearance. Constant LMS lightnesses generate constant colors. That hypothesis led to a study of color appearances in L, M, S bands of light. Do all red colors have the same triplet of

lightness appearances? Does a red color always look [light, dark, and dark] in L, M, S light? Does a green always look [dark, light, and dark]? Does color appearance always correlate with the triplet of L, M, S lightnesses?

The experiment is easy. Find narrowband red, green, and blue filters. Be sure that the filters exclude the other two-thirds of the spectrum. With a green filter, you should just see greens with different lightnesses. You should not see a mixture of green and yellow and blue hues. If you do, you need a filter with a narrower band of transmission.

Identify a group of red objects. Look at them sequentially through the L, M, S filters. Look at them in different ambient illuminations. Look at them at different times of the day. Look at them in sunlight and shadows. Red colors are always (light, dark, and dark) in L, M, S light. The same dependence of the triplet of L, M, S lightnesses holds for all colors (Table 1). Lightness is the output of spatial image processing. It is the result of post-receptor spatial processing. That is why lightness does not correlate with cone quanta catch. However, color does correlate with three lightnesses in long-, middle-, and short-wave light.

Retinex Theory, Table 1 Correlation table of color appearances and the apparent lightnesses in L, M, S illumination

Color Appearance	Appearance in L- light	Appearance in M- light	Appearance in S- light
Red	light	dark	dark
Yellow	light	light	dark
Green	dark	light	dark
Cyan	dark	light	light
Blue	dark	dark	light
Magenta	light	dark	light
White	light	light	light
Black	dark	dark	dark

Retinex Theory, Fig. 5

(Top-left) Red color squares on white and (top-center) color assimilation experiments change the appearance of the red squares; (bottom) L, M, S separation images. Color appearances of red squares correlate with L, M, S lightnesses

Retinex theory predicts that the triplet of L, M, S lightnesses determines color. Colors are constant with changes in illumination because the triplet of lightnesses is nearly constant.

Land’s observation still stands: The triplet of lightnesses correlates with color. The observation is important because a variety of different phenomena can influence lightness, such as simultaneous contrast, the Cornsweet effect, and assimilation. Regardless of the cause of the lightness changes, when two identical physical objects look different, color appearances correlate with their L, M, S lightnesses ([7], Section E).

In the color assimilation display (Fig. 5), there are two sets of nine red squares that have the same reflectance and appear the same (top left).

However, if these red squares are surrounded by yellow and blue stripes, they look different (top center): The left red squares fall on top of the yellow stripes, and the right ones on the blue stripes. The left squares appear a purple red, while the right ones appear a yellow orange. In other words, the left squares appear more blue and the right ones more yellow.

In Fig. 5 (bottom-left), in the L separation, corresponding squares are lighter on the right of the separation; in the M separation, these patches are lighter; and in the S separation, they are darker on the right. Land’s Retinex predicts that whenever L and M separations are lighter and S separation is darker, the patch will appear more yellow (see right squares in assimilation

experiment (top-center)). Whenever S separation is lighter and L and M separations are darker, the patch will appear more blue (see left squares in assimilation experiment (top-center)). Colors correlate with L, M, S lightnesses ([7], pp. 221–281).

Retinex Image Processing

Land described that the fundamental challenge of color vision shifted to the ability to predict lightness, i.e., the spatial interactions in each color channel found in postreceptor neural processes. In 1967, Land and McCann proposed a computational model for calculating lightness from the array of all scene radiances [6]. The model compared each pixel with every other pixel in an image. The goal was to calculate the sensation of image segments that equaled what observers saw. In the past 50 years, there have been many implementations and variations of this process. They are called Retinex algorithms. It is curious that Land reserved the use of the term “Retinex” to describe three independent lightness channels. Today’s usage of the word includes a much wider range of computer algorithms that build calculated appearances out of arrays of radiances.

To calculate lightnesses in complex scenes, one must:

- Capture radiances from the entire scene.
- Convert scene radiances to cone and rod quanta catches.
- Calculate lightness for each color channel using all pixels in the scene.
- Compare calculated lightnesses with observer matches.

The Land and McCann model [6, 9, 11, (7, pp. 293–337)] used:

- Edge ratios of cone quanta catches (basic building block).
- Gradient threshold (found to be unnecessary in later studies).
- Multiplication of edge ratios (makes long-distance interactions).

- Reset to maxima (scaled the output).
(introduced dependence on scene content, e.g., simultaneous contrast)
- Average of many spatial comparisons.

The first computer implementation of the model in the early 1970s used an array of 20 by 24 pixels. McCann, McKee, and Taylor showed that long-, middle-, and short-wave computed lightnesses predicted observer matches of color Mondrians in color constancy experiments [8].

Since the late 1960s, computer imaging has shown remarkable advances. Digital images have replaced film in most of photography. Computer graphics has made image synthesis ubiquitous. Retinex image processing has grown with the advances in digital imaging [9–11]. In the early 1980s, Frankle and McCann introduced a multiresolution algorithm that allowed efficient comparison of all pixels in a 512 by 512 pixel image [12]. Multiresolution software programs (Zoom Retinex) calculate all scene lightnesses with $O(N)$ computational efficiency [9]. Sobol extended Frankle and McCann’s algorithm in the design of commercial digital cameras [13] introduced in 2003. Other applications used Retinex’s efficient spatial processing for color gamut-mapping [14].

Using different approaches, Jobson and Kotera have studied the NASA Retinex. Rizzi and colleagues have developed the Milan Retinex ([7], pp. 324–328).

The important feature of real complex scenes is that the illumination is rarely uniform. Shadows and multiple reflections increase the dynamic range of light coming to our eyes, and to cameras. The application of Retinex algorithms to high dynamic range (HDR) scenes has become a major topic of research and engineering applications ([7], pp. 283–375). The limits of HDR scene capture and reproduction are controlled by optics, namely, optical veiling glare. Camera glare limits the range of light on the sensor, just as intraocular glare limits the range of light on the retina. The scene content controls the distribution of glare range of light in images. Vision’s postreceptor neural processes compensate for veiling glare ([7],

pp. 89–171). That explains humans' high dynamic range of appearances from low-dynamic-range retinal images. The spatial mechanisms modeled by Retinex algorithms play a major role in compensating for glare and generating our range of color and lightness sensations [15, 16].

Over the years, many variations of spatial processing mimicking human vision have been called Retinex algorithms.

Signatures of Color Constancy

Studies of color constancy have documented its limits. Measurements of departures from perfect constancy provide a signature of the underlying postquantum-catch neural mechanisms. Land's double Mondrian experiments used spatially uniform illumination with different spectral compositions. In each spectral, illuminant observers chose matching Munsell chips very close to the actual Munsell papers in the Mondrian areas, indicating near-perfect constancy. Nevertheless, each spectral illuminant had different small systematic departures from perfect constancy across the entire Mondrian [8]. Similar small departures were observed in experiments with color adapting surrounds, again in uniform spatial illumination ([7], pp. 239–245). A pair of recent experiments measured color constancy using two identical 3D Mondrians made of blocks of wood painted with 1 of 11 matte paints. The experiments used different illuminations. The first used a diffusing tent that minimized shadows – the low-dynamic-range (LDR) scene. The second used spotlights that made sharp shadows – the high-dynamic-range (HDR) scene. Observers reported a marked loss of color constancy in 3D Mondrians. LDR illumination caused a substantial loss of constancy in some local regions; HDR illumination caused a much larger loss in other regions [17]. The appearance of a surface in 3D blocks no longer shows universal correlation with the paint's surface reflectance when the illumination introduces quanta-catch edges. These and other experiments support Retinex's spatial comparison mechanism [18]. Five different studies of the signatures of color appearance in real scenes demonstrate the

important role of spatial comparisons in vision [19].

Summary

Edwin Land coined the term Retinex in 1964 as the name of human color channels that build up appearance from spatial comparisons. Over the years, others have redefined the term to include many different spatial algorithms that attempt to mimic human spatial color processing. Land's Retinex was built to model color constancy. Over the years, quantitative measurements of the limits of constancy have provided signatures of the underlying visual mechanism. These signatures support neural spatial comparisons within color channels.

Richter, Manfred

Rolf G. Kuehni
Charlotte, NC, USA

Biography

Richter was born on August 7, 1905, in Dresden, Germany, where he studied technical physics under Robert Luther at the Technical University from 1924 to 1933. The subject of his doctoral dissertation was Goethe's *Farbenlehre* as related to scientific problems. [1] In 1927, as an assistant in the department of color research of the German Institute of Textile Research and following Helmholtz' assistant Arthur König, he developed an international bibliography of publications in color science, an effort he continued until the mid-1950s [2]. In 1934, he began work in the laboratories of the lamp manufacturer OSRAM in Berlin. In 1943, he transitioned to the *Materialprüfungsanstalt* (Office for testing of materials), later named *Bundesanstalt für Materialprüfung* (BAM), where he remained until 1962 and where he organized a color research laboratory. In 1941, he was asked by *Deutsches Institut*

für Normung (DIN, German institution for industrial standards) to develop a standard color system and atlas, an effort that kept him occupied for an extended period of time. It is known as DIN6164 today. He was also a professor at the *Institut für Lichttechnik* (Institute for lighting technology) of the Berlin Technical University. In 1949, he was a founding member of the *Fachnormenausschuss Farbe* (FNF, Color standards committee). He was a leading member of *Deutsche farbwissenschaftliche Gesellschaft* (DfwG, German society for color science, founded in 1974) and a founding member of the journal *Die Farbe* (1951–2003). He was a member of the directorial board of the International Association of Colour (AIC) and active in several research committees of the International Association of Illumination (CIE). His passing on April 20, 1990, was the result of a traffic accident.

Major Accomplishments/Contributions

DIN6164: Richter’s plan for a standard object color system and atlas was that it needed to be based on well-supported colorimetric data and the latest insights into color order. A starting point was Ostwald’s color atlas and the Luther-Nyberg optimal object color solid. The system was to be perceptually uniform. As perceptual parameters he

Richter, Manfred, Fig. 2 3D representation of the samples of the DIN6164 system. © Eckhard Bendin

selected hue (T), saturation (S), and degree of darkness (D). Lacking a satisfactory colorimetric model of hue scaling he proceeded to experimentally determine a constant saturation contour in the CIE chromaticity diagram separated into 24 perceptually equal hue differences. He then scaled saturation

from the neutral point to the spectral limit into up to 16 levels. The darkness scale D is based on logarithmic scaling of the relative brightness value scale proposed in 1928 by S. Rösch. It has a value of 0 for white and 10 for black. A schematic cross section of the system is shown in Fig. 1.

Atlases were published in 1960/62 with matte samples and 1978/83 with glossy samples. Figure 2 shows a 3D model of the system. As its name indicates, DIN6164 is a German industrial standard system.

Publications: In 1940 Richter published a book on color science, with the cooperation of I. Schmidt and A. Dresler, that presented the subject in at that time likely the most comprehensive and detailed form. [4] Given the Second World War it was never translated into English. In 1976, he published *Einführung in die Farbmatrik* (Introduction to color metrics) [5].

Highway lighting; Public lighting; Roadway lighting; Street lighting

Definition

Road lighting is the application of illumination systems along roadways, primarily for the purpose of improving safety by increasing visibility of roadside hazards and by reducing the effects of glare from other light sources in the visual environment, such as vehicle headlamps.

Introduction

Road lighting systems are an important part of the highway safety infrastructure across the world. Two important purposes of road lighting are to allow drivers to see the roadway further ahead than their own vehicle's headlamps allow and to reduce glare from other vehicles' headlamps [1]. Indeed, road lighting is generally associated with reduced nighttime crash rates [2, 3], and the presence of illumination that results in increased luminances of potential road hazards can reduce the impact veiling luminances produced by bright sources of light in the driver's field of view. In the present article, existing practices and standards for road lighting are described, as well as the light source and luminaire technologies used to provide road lighting. For further details on road lighting and interactions with other visual information systems, consult references [4, 5].

Practices and Standards

CIE 115

In most of the world, the primary road lighting standard is the Commission Internationale de l'Éclairage (CIE) *Lighting of Roads for Motor and Pedestrian Traffic*, CIE 115 [6]. In CIE 115, three main lighting classes are specified: for motorized traffic (M), for conflict areas between vehicles or between vehicles and pedestrians (C), and for pedestrian traffic (P). Each main class is subdivided into numerical classes based upon factors such as traffic volume and speed, road access control, ambient environment, and the mix of motorized and pedestrian traffic. Lower-numbered classes refer to more complex road situations requiring higher light levels.

Specifications for M classes M1 through M6 are given in average road surface luminance and range from 2 to 0.3 cd/m^2 . For C classes C0 through C5, illuminance specifications range from 50 to 7.5 lx. For P classes P1 through P6, illuminance specifications range from 15 to 2 lx. CIE 115 specifications also include limits for characteristics such as uniformity, glare, and, when facial recognition of pedestrians is important, vertical illuminance [6].

CIE 115 also provides a method for the specification of adaptive lighting to account for the possibility of reduced vehicle or pedestrian traffic at certain times throughout the night [6]. Light levels can be reduced to different classes, resulting in decreased energy use and light pollution.

Road lighting calculations are often performed using software that accepts a photometric file containing tabulated luminous intensity data for a luminaire. For a set of road geometric characteristics, pole locations and heights, the software calculates the illuminances or luminances, uniformities, and veiling luminances. Such calculations should account for lamp output reductions and dirt accumulation over time. The light output from a road lighting system could be 20–30% lower after several years than when it was new and clean.

RP-8

In North America, the primary standard for most road lighting is the Illuminating Engineering Society (IES) *Recommended Practice for Design and Maintenance of Roadway and Parking Facility Lighting*, RP-8 [1]. RP-8 serves as the basis for continuous road lighting system by the American Association of State Highway and Transportation Officials [AASHTO [7]], which provides warrants for road lighting based on traffic volume and crash frequency at night. RP-8 includes different specification methods for different facility types in terms of the luminance of the roadway surface. There are also requirements for uniformity of luminance and limits to control for glare in terms of veiling luminance.

The target light levels depend upon the road type (i.e., local, collector, major, or freeway) and the pedestrian conflict level. For example, for a

local road with a medium pedestrian conflict level, the average luminance should be at least 0.5 cd/m^2 , the minimum luminance no less than 1/6 the average, and the veiling luminance should not exceed 40% of the average road surface luminance [1]. For a major roadway with the same pedestrian conflict level, the average luminance should be at least 0.9 cd/m^2 , the minimum luminance should be no less than 1/3 the average, and the veiling luminance should not exceed 30% of the average road surface luminance [1]. Calculations for RP-8 road lighting criteria are performed similarly as for CIE 115 criteria.

RP-8 criteria are for continuous lighting along roads excluding intersections and interchanges. Intersection lighting criteria are given in terms of illuminances on the road surface, based on the types of intersecting roads. Like CIE 115, RP-8 permits the implementation of adaptive lighting when pedestrian (or vehicular) use changes throughout the night.

Light Sources

Road lighting systems can use a wide variety of light sources. At present (as of 2019) most road lighting installations use discharge sources (high- and low-pressure sodium, metal halide, fluorescent, and induction lamps). Increasingly, however, solid-state (light-emitting diodes) sources are being used for road lighting. Several common light sources for road illumination are illustrated in Fig. 1.

High-Pressure Sodium

High-pressure sodium (HPS) lamps emit light when a current is applied to sodium vapor. The inner envelope of an HPS lamp contains sodium, and the outer glass bulb absorbs ultraviolet (UV) energy and stabilizes the arc tube temperature. HPS lamp efficacies are high, and they have long operating lives and very high lumen maintenance. HPS lamp illumination is yellowish in color. “Whiter” HPS lamps can be developed by increasing the sodium vapor pressure or operating HPS lamps at high frequencies. HPS lamps are the most common sources used in road lighting. For

Lighting Research Center). (d) Two light-emitting diode (LED) packages (Courtesy of the Lighting Research Center)

additional details about the performance of HPS lamps, consult the entry ► [“High- and Low-Pressure Sodium Lamp”](#) in this Encyclopedia.

Metal Halide

Metal halide (MH) lamps have an arc tube containing various metallic halide compounds in addition to mercury, which emit light across the visible spectrum. MH lamps have relatively high efficacy and are available in a range of white colors ranging from “warm” to “cool” in appearance. Lamp life is typically not as high as HPS lamps but has been improving substantially in recent years. Lumen maintenance values range from fair to good. MH lamps with ceramic arc tubes and improved starting gear are available, which have much-improved life and lumen maintenance. For additional details about the performance of MH lamps, consult the entry ► [“Metal Halide Lamp”](#) in this Encyclopedia.

Low-Pressure Sodium

Like HPS, low-pressure sodium (LPS) lamps use sodium vapor but at a much lower vapor pressure. LPS lamps are linear in shape. They produce nearly monochromatic yellow light near 589 nm. They have relatively long operating lives, excellent lumen maintenance, and very high luminous

efficacy, although color rendering is essentially nonexistent with these lamps. LPS lamps are sometimes used near astronomical observatories because it is fairly easy to filter out the wavelengths emitted this source. LPS is more common in Europe than in North America for road lighting. For additional details about the performance of LPS lamps, consult the entry ► [“High- and Low-Pressure Sodium Lamp”](#) in this Encyclopedia.

Fluorescent and Induction

Fluorescent lamps are low-pressure gas discharge sources. Light is produced by fluorescent phosphors activated by ultraviolet energy from a mercury arc. Fluorescent lamps have reasonably long operating lives, limited primarily by the life of the lamp end electrodes that generate the electrical discharge. Fluorescent lamps require ballasts to provide the starting and operating voltages and currents needed for proper lamp operation. Fluorescent lamp color of fluorescent lamps is determined by the phosphors used to coat the envelope. Fluorescent lamps have relatively higher luminous efficacies and lumen maintenance values.

A special fluorescent lamp type, the induction lamp, has found some success for road lighting. Induction lamps have somewhat more compact shapes than tubular fluorescent lamps because

they use a magnetic induction coil to provide the current that stimulates the mercury vapor inside the lamp. Typical operating lives are double or triple those of fluorescent lamps, with luminous efficacy comparable in value. For additional details about the performance of fluorescent and induction lamps, consult the entries ► [“Tubular and Compact Fluorescent Lamp”](#) and ► [“Induction Lamp”](#) in this Encyclopedia.

Light-Emitting Diodes

Light-emitting diodes (LEDs) are solid-state semiconductor junction devices that emit light when a current is passed through the junction. White light can be created by mixing light from red, green, and blue LEDs, or by using blue LEDs with phosphors that convert some of the blue light into yellow light, resulting in a mixture that is perceived as white. Newer LED packages exist in addition to 5-mm diameter epoxy capsule LEDs used for indicator lights. Some packages contain metal heat sinks to dissipate internal temperatures, which can reduce LED light output and shorten operating life. LED lighting technology is increasing in luminous efficacy and LEDs also have very long operating lives with gradual reductions in light output over time. For additional details about the performance of LEDs, consult the entry ► [“Light-Emitting Diode, LED”](#) in this Encyclopedia.

Luminaires

Road lighting systems generally consist of pole-mounted luminaires, usually with individual photocell or timer control. The most common luminaire type used for road lighting is the so-called cobrahead luminaire (Fig. 2), named for its distinctive shape. Figure 3 shows typical road luminaire construction. Luminaires are designed for a particular type of light source such as discharge lamps including HPS or MH [8], and there is increasing interest in induction and especially LED luminaire systems [9, 10].

Luminaires for road lighting can be classified in several ways. A cutoff classification system [1], used by many North American road lighting specifiers, classifies luminaires according to their

Road Lighting, Fig. 2 Cobrahead luminaire for road lighting (Courtesy of the Lighting Research Center)

luminous intensity distributions in different angular regions (relative to nadir, defined as 0° directly below the luminaire) where light output could contribute to glare or light pollution. Table 1 summarizes the luminous intensity limits (in cd) for different cutoff classifications, relative to the light output (in lm) of the lamp inside the luminaire. The IES has adopted a system to classify the distribution of light from an outdoor luminaire that simply uses the amount of light output (in lm) emitted within various angular regions to serve as the basis for classification [12].

As mentioned previously, the most common control system for roadway lighting is a photocell mounted to an individual luminaire, which will switch the luminaire on and off at a specified ambient light level. Some systems will use centralized control via a single photocell or time clocks. Technological innovations are making centralized control systems attractive, because these systems can also monitor performance of individual luminaires and alert the system operator when a lamp or ballast failure has occurred or is close to occurring [13]. They can also be useful in controlling adaptive road lighting systems.

Color: Mesopic Vision

The color of the light source used for road lighting can influence visual perception of drivers and pedestrians. Although photometric specifications for road lighting are based on the photopic luminous efficiency function, representing the spectral sensitivity of cone visual photoreceptors to light at daytime light levels, visual spectral sensitivity differs at low levels commonly experienced under road lighting at night. At very low light levels, rod photoreceptors, whose sensitivity is represented by the scotopic luminous efficiency

Road Lighting,

Fig. 3 Components within a typical road lighting luminaire (Courtesy of the Lighting Research Center)

Road Lighting, Table 1 Light output limits for luminaire cutoff classifications [11], given in luminous intensity values (in cd) as a percentage of the luminaire’s lamp lumens (in lm)

Cutoff type	Light between 80° and 90°	Light above 90°
Full cutoff	100 cd per 1,000 lm	None
Cutoff	100 cd per 1,000 lm	25 cd per 1,000 lm
Semicutoff	200 cd per 1,000 lm	50 cd per 1,000 lm
Noncutoff	No limitation	No limitation

function, dominate vision. At many road lighting levels, both rods and cones contribute to vision and luminous efficiency can be approximated by a combination of photopic and scotopic efficiency [14].

As a consequence, light sources with relatively greater power in the short-wavelength portion of the visible spectrum can be more effective for vision at these so-called mesopic, nighttime light levels. Lamp spectra can be characterized by their scotopic/photopic (S/P) ratio [15], which

Road Lighting, Table 2 Scotopic/photopic (S/P) ratios of common light sources [14, 15]

Light source	S/P ratio
HPS 250 W clear	0.63
MH 400 W clear	1.51
LPS	0.25
Fluorescent/induction (“cool white”)	1.48
LED (4,300 K)	2.04

indicates a light source’s ability to stimulate the rods for an equivalent amount of cone stimulation. Table 2 lists S/P ratios for several road lighting sources. The CIE has developed a unified system of photometry [15] bridging the photopic and scotopic systems, as part of CIE Publication 191 [15], to quantify mesopic luminance. Above a luminance of 5 cd/m², the unified luminance and the photopic luminance are equivalent, and below a luminance of 0.005 cd/m², the unified luminance and the scotopic luminance are equivalent. The CIE 191 system uses the photopic luminance and the S/P ratio of the light source under investigation to estimate the unified luminance.

Runge, Philipp Otto

Rolf G. Kuehni
Charlotte, NC, USA

P. O. Runge, Self-portrait, ca. 1804

Biography

Runge was born on July 23, 1777, the 9th of 11 children of a tradesman and cargo ship owner and his wife in Wolgast, Pomerania, on the Baltic Sea, then under Swedish rule. As a child he was frequently ill with tuberculosis, being often educated at home. In 1795 he began a commercial apprenticeship at his older brother Daniel's firm in Hamburg. In 1799 Daniel supported Otto financially to begin the study of painting at the Copenhagen Academy. In 1801 Otto moved to Dresden to continue his studies, where among others he met his future wife Pauline Bassenge and the painter Caspar David Friedrich. He also began to study extensively the writings of the seventeenth-century mystic Jakob Boehme. In 1803, on a visit to Weimar, Runge unexpectedly met Johann Wolfgang von Goethe, and the two formed a friendship based on their common interests in color and art. After marrying Pauline in 1804, they moved to Hamburg. But due to imminent war dangers (Napoleonic siege of Hamburg), they relocated in 1805 to his parental home in Wolgast where they remained until 1807, then returned to Hamburg. Together they had four children, the last born on the day after Runge's premature death in 1810. In March of 1810 Runge became ill with tuberculosis again to which he succumbed on December 2 of the year. Runge was of a mystical, deeply Christian turn of mind, and in his artistic work he tried to express notions of the harmony of the universe through symbolism of color, form, and numbers. He considered blue, yellow, and red to be symbolic of the Christian trinity, equating blue with God and the night; red with morning, evening, and Jesus; and yellow with the Holy Spirit (Runge 1841, I, p. 17 [1]). During his short life he became one of the most important German painters of the Romantic period.

Major Accomplishments/Contributions

Runge's interest in color was the natural result of his work as a painter and of having an

enquiring mind. Among his accepted tenets was that "as is known, there are only three colors, yellow, red, and blue." (letter to Goethe of July 3, 1806) [2]. His goal was to establish the complete range of colors resulting from mixture of the three primaries, among themselves and together with white and black. In the same lengthy letter, Runge discussed in some detail his views on color order and included a sketch of a mixture circle, with the three primary colors forming an equilateral triangle and, together with their pair-wise mixtures, a hexagon. He arrived at the concept of the color sphere sometime in 1807, as indicated in his letter to Goethe of November 21 of that year, by expanding the hue circle into a sphere, with white and black forming the two poles [3]. A color mixture solid of a double-triangular pyramid had been proposed by Tobias Mayer in 1758 and implemented in form of a triangular pyramid by J. H. Lambert, facts known to Runge. His expansion of that solid into a sphere appears to have had an idealistic basis rather than one of logical necessity. In 1808 he hoped to provide scientific support for the sphere form with disk color mixture experiments. Encouraged by Goethe and other friends, he wrote in 1808 a manuscript describing the color sphere, published in Hamburg early in 1810 as *Farben-Kugel* (Color sphere) by his friend Friederich Perthes [4]. An included hand-colored plate shows two different views of the surface of the sphere as well as horizontal and vertical slices demonstrating the organization of its interior (Fig. 1).

In addition to a description of the color sphere, it contains an illustrated essay on rules of color harmony by Runge and one on color in nature written by Runge's friend Henrik Steffens. Runge's premature death limited the impact of this work. Goethe, who had read the manuscript before publication, mentioned it optimistically in his *Materialien zur Geschichte der Farbenlehre* of 1810 as "successfully concluding this kind of effort" [5]. More detailed similar systems were published soon thereafter

Rushton, William A. H.

Stephen Westland

Colour Science and Technology, University of Leeds, Leeds, UK

William Albert Hugh Rushton was a British physiologist who made important contributions to our understanding of color vision and perception. He is perhaps best known now for his development of the principle of univariance.

Rushton was born in London on 8 December 1901. He entered Cambridge University as a medical student in 1921 and obtained a degree in physiology in 1925. He received a PhD degree in 1928 working under Prof. E.D. Adrian for his research investigating the flow of current in and around nerves to determine the portion of the current responsible for excitation. As a result of this work he won the Stokes Studentship at Pembroke College in 1929. He spent 2 years at the Johnson

Foundation in Philadelphia before returning to a Research Fellowship at Cambridge University. He went to University College Hospital in 1931 to study clinical medicine before obtaining a Lectureship at Cambridge University in 1935 after which he produced a prodigious body of work; he published 37 papers on nerve with 4 colleagues over 25 years and 147 papers on vision with 27 colleagues over a period of 30 years. Upon retirement he spent some time at Florida State University as a Distinguished Research Professor. He was awarded the Royal Medal of the Royal Society in 1970 and continued to publish until he died in June 1980.

Nervous Excitation

Rushton laid the groundwork for the establishment of the modern theory of nervous excitation and propagation by his quantitative analysis of the temporal and spatial factors involved in electrical excitation [1, 2].

Retinal Densitometry

He developed techniques to measure the visual pigments *in vivo*. And made important contributions regarding the distribution of pigments in the retina, the action spectrum of bleaching, and the spectral characteristics of bleaching [3–5].

Cone Pigments

By 1955, Rushton had evidence of visual pigments at the fovea in normal and color-blind subjects. He obtained evidence of two pigments in the medium-long wavelength spectrum in color normals and demonstrated that protonopes and deuteranopes were each lacking one of these pigments [6, 7].

Analytical Anomaloscope

In the early 1960s, Rushton developed an analytic anomaloscope to study color vision. Using this

instrument, observers would match a pure spectral light with an additive mixture of red and green in variable proportions [8].

Principle of Univariance

Rushton published two papers in *Scientific American* and gave several notable didactic lectures. In a review lecture at the Physiological Society (London), he described the principle of univariance that: “the output of a receptor depends upon its quantum catch, but not upon which quanta are caught.” Many of the laws of color mixing are a direct consequence of this principle. He also reintroduced the cone pigment triangle, first put forward by Maxwell, as an alternative to the usual representation of color space developed by the CIE [9].

RYB Color

Zena O'Connor
Design Research Associates, Sydney, NSW,
Australia

Synonyms

Designer's color model; Painter's color model;
RYB triad; Traditional color model

Definition

A cornerstone component of traditional color theory, the RYB conceptual color model underpins the notion that the creation of an exhaustive gamut of color nuances occurs via intermixture of red, yellow, and blue pigments, especially when applied in conjunction with white and black pigment color. In the literature relating to traditional color theory and RYB color, red, yellow, and blue are often referred to as primary colors and represent exemplar hues rather than specific hues that are more pure, unique, or proprietary variants of these hues. Under traditional color theory, the RYB color model is accompanied by a range of hierarchical color constructs and color combination constructs.

Categories of Color

Green-Armytage identified a number of color categories, and each of these is underpinned by specific and distinct ontological and epistemological assumptions and traditions [1]. These categories include conventional color, substance color, formula color, spectral profile color, psychophysical color, inherent color, and perceived color. In relation to these categories of color, RYB color falls under the specific category of substance color.

Traditional Color Theory

Traditional color theory is just one of various branches of color theory, and each of these branches tends to relate to a specific category of color, as detailed above [2]. Gage notes that a number of factors distinguish traditional color theories and sets these aside from other color theories: (a) an ontological focus on pigment color exploration and application in art, design, and architecture; (b) consideration of an exemplar set of primary pigment colors from which a large gamut of color nuances can be created; (c) a focus on creating and applying color harmony; and (d) the provision of color combination guidelines for color exploration and application [3].

Hierarchical Color Classifications

Under traditional color theory and the RYB color model, hierarchical color classifications are evident. The first of these classifications is referred to in the literature as “primary,” “principal,” “simple,” or “basic” colors, and in respect to RYB color these are red, yellow, and blue. The next level is referred to as “secondary” or “compound” colors, representing intermixture of primary colors, and under traditional color theory and RYB color these are orange, green, and purple. A third hierarchical level is referred to as “tertiary” color, representing an intermixture of red, yellow, and blue in varying proportions [2–19].

In respect to the RYB color classification of “tertiary” color, Ruskin muddled this term and contradicted the common understanding of the term by suggesting that “tertiary” colors were those that lay *between* “secondary” colors as this enabled him to avoid what he termed *tiresome* color names, an example of misleading definition that continues today [2, 20].

Origins and Development of RYB Color

Aside from commentary offered by ancient Greek philosophers, Tobias Mayer is credited with

RYB Color, Fig. 1 RYB color model (Illustration by Zena O'Connor and Geoffrey Gifford 2021)

conceptualizing and documenting the first RYB color model base [4–6].

Multiple traditional color theorists since Mayer presented color models based on the RYB triad supported by detailed rationale and discussion including Moses Harris, Philipp Otto Runge, George Field, Charles Hayter, J.L.F. MÉRIMÉE, Michel-Eugène Chevreul, Albert Munsell, Johannes Itten, and Josef Albers [7–21]. In this context, the ontological focus of RYB color remained substance (pigment color) and, in particular, specific types of pigment color such as gouache. Media such as this had the capacity to create a large gamut of color nuances via intermixture of the RYB triad as well as flat areas of opaque color with “hard” edges suitable for professional design output. The RYB color model was widely applied across multiple industry sectors up until the emergence of digital color technologies in the twentieth century.

The RYB color model did not feature a methodology to identify and communicate color information across different applications or industry sectors. Initially, color matching was conducted manually, but the unreliability of this process proved problematic for those applying color across diverse applications due to color mismatch issues. As a result, color notation systems were developed to aid identification and specification of

color including the Munsell color notation and color atlas (initially published 1905, 1913), the RAL color system (launched 1927), the Pantone PMS system (launched 1963), and the NCS color system (launched 1979) [22–24].

RYB Color Model

The RYB color model often reflects the format of other color models such as RGB and CMY. However, each of these color models is distinctly different, in terms of ontology and epistemological traditions, and should not be conflated or used substitutionally in any way. RYB color emerged from traditional color theory and relates to substance (pigment) color while RGB color relates to spectral profile color and visual perception of color; meanwhile, the CMYK model emerged from the way in which color is printed using various techniques common in the printing industry.

The RYB model featured in Fig. 1 is illustrated in Venn diagram format to differentiate it from other color models, whereby three exemplar pigment colors (red, yellow, and blue) represent primary and distinct components (x , y , and z), isolated via gray boundaries. Three secondary exemplar pigment hues (orange, green, and

purple) are achieved through intermixture of primary pigment hues ($x + y$, $y + z$, and $z + x$). These differentiated component sections can be considered *minterms*, or a logical conjunction of the three distinct primary component sections. As such, these minterm component sections do not represent a semitransparent overlay of primary hues arising from additive mixture of hues as per the RGB color model. Instead, the minterm components represent representative hues which are intended to represent a multitude of the potential intermixed hue nuances of orange, green, and purple. The central component represents a tertiary color achieved via intermixture of all three primary pigment hues ($x + y + z$). This tertiary color appears a murky grayish brown but can vary considerably in hue and value depending on the proportional intermixture of primary pigment hue colors.

As with similar color models, the RYB color model is a highly simplistic conceptual model which is not intended to illustrate the complexity of color or the multitude of hue nuances achievable via pigment color intermixture but a simple illustrative model of basic color creation and intermixture.

RYB Triad

► [RYB Color](#)

Saltzman, Max

Ellen C. Carter
Color Research and Application and, Konica
Minolta, Pennsville, NJ, USA

Max Saltzman was a chemist, educator, and scholar. As a steadfast member of the color community in the USA, he often mentored colleagues with thoughtful and generous encouragement, which resulted in him having a profound influence in the field of color science in both industry and the art community.

Saltzman received a B. S. degree in chemistry from the College of the City of New York in 1936. In this early period he worked in the field of medical instrument research and during the war

years was in civilian service with the Chemical Warfare Service. Following the war he settled into his first career in color by joining Harmon Colors, which later became Allied Chemical Corporation, where he worked in various research and management capacities for 26 years. As a native New Yorker, he lived in the city and reverse commuted to New Jersey for this entire time period.

At Harmon he became an expert in pigments, dyes and resins by identifying the colorants, making objective color measurements, defining criteria for selection of colorants for specific applications and use of computers for color matching. We can see his interest and influences through the organizations which he joined: The American Chemical Society, the American Association of Textile Chemists and Colorists, the Inter-Society Color Council, the Society of Plastic Engineers, the Optical Society of America, the Society of Dyers and Colorists (U.K.), the Color Group (Great Britain), the Dry Color Manufacturers' Association, and the Federation of Societies for Coatings Technology.

During this time, Saltzman realized there was a need for academic and industrial training in color technology. He encouraged Dr. Walter Bauer, Dean of the College of Science at Rensselaer Polytechnic Institute to establish a new research laboratory at RPI and to recruit Dr. Fred W. Billmeyer, Jr., to run the undergraduate and graduate program in color science and to expand it to include summer short courses for people from industry. The very popular textbook, *Principles of Color Technology* by Fred W. Billmeyer and Max

Saltzman went through two editions during this period (1966 and 1981) and followed Saltzman's teaching principles of going back to the basics for a thorough understanding of the issue. Saltzman served as an Adjunct Professor for most of the 20 years the Rensselaer Color Laboratory was in existence.

Upon retiring from Allied Chemical in 1973, Saltzman left New York, moving to the west coast where he found time to follow one of his other major interests: the study and identification of ancient dyestuffs in textiles. He began by establishing a color identification laboratory in the Institute of Geophysics and Planetary Physics at the University of California. His research led him to far and wide, for example, he traveled to Peru to collect authentic samples of dyes used in ancient Peruvian textiles. This soon led to his second career in the area of conservation of historical textiles and other objects. He became active in the American Institute for Conservation of Historic and Artistic Works and the International Institute for Conservation of Historic and Artistic Works. In 1984, he was invited to present the George L. Stout Memorial Lecture, a prestigious honor from the American Institute for Conservation of Historic and Artistic Works. When the J. Paul Getty Conservation Institute was established, Saltzman became a consultant there.

Although often working behind the scenes with individuals, Max Saltzman became an internationally recognized authority in the field of color science, receiving the Armin J. Bruning Award (1969) and the Inter-Society Color Council Macbeth Award (1986). Among his many recognitions and awards, the Inter-Society Color Council also honored Max Saltzman's lifetime of contributions by bestowing on him the 2001 Godlove Award. Sadly, he died before the ceremony to receive the award.

Sampling Problems in Computer Graphics

Kartic Subr

Department of Computer Science, University College London, London, UK

Definition

The term “sampling” is ambiguous since it lends itself to a multitude of interpretations across various fields of study. In computer graphics, sampling problems arise in two distinct contexts. First, continuous functions (signals) are discretized via sampling. For example, a pixelated image represents an underlying continuous image signal sampled at the grid of pixel locations. The general problem is then of reconstructing a high-fidelity approximation of the continuous signal using the discretization. This application of sampling is heavily inspired by the wealth of literature in the digital signal processing community [1]. The second category of sampling problems in

computer graphics applications uses sampled values to estimate general characteristics of the sampled population [2]. For example, in Monte Carlo image synthesis, samples of the radiance incident at each pixel are used to estimate the expected radiance at the pixel, using Monte Carlo integration. This article addresses the relevance and application of each of these classes of sampling problems across various topics in computer graphics.

Two Categories of Sampling Problems

The core problem of sampling a continuous domain involves the selection of a finite set of points in the domain. The sample locations may be chosen by a deterministic algorithm or a stochastic algorithm. The evaluation of a function, defined over this domain, at these sample locations is commonly known as sampling the function. Numerous strategies exist for sampling. The relative benefits of these strategies hinge on the use of the resulting samples.

In computer graphics, the functions are sampled for two purposes (Fig. 1). First, sampled functions are sometimes the only tractable representation for the function under consideration. For example, images are rendered by computing the

amount of light at each pixel on a grid. The second purpose of sampling is to glean key attributes of the function from its sampled values. For example, the expected amount of incident light (radiance) at each pixel is estimated by sampling the infinite space of light paths arriving at that pixel from virtual light sources in the scene. Another example of statistical sampling in graphics is in usability testing, for subjective evaluation, such as rating intuitive interfaces, judging the relative quality of images, etc. This article presents an overview of sampling problems that arise in computer graphics. In addition, it briefly describes the approaches adopted for analysis and assessment of the sampling algorithms. Regardless of the use of the sampled function, the representation of the function by evaluations at a finite set of locations introduces errors. A systematic characterization of these errors is important for assessing and comparing sampling strategies.

Discretization: Sampling for Reconstruction

Discrete representations are ubiquitous in computer graphics: Images are represented by a spatial grid of locations; the distribution of radiant light energy across wavelengths is often represented

Sampling Problems in Computer Graphics, Fig. 1 Sampling is the process of identifying a set of points (red circles) in the domain of a function. Sampled functions are function values (purple circles) evaluated at the sampled points. In computer graphics, sampled

functions are used for two general purposes: reconstruction of the function (blue curve) and for estimation of characteristics of the function, such as the area under its curve (e.g., the green shaded area)

Sampling Problems in Computer Graphics, Fig. 2 The errors, or artifacts, due to the discretization of a continuous function is called *aliasing*. The zone plate function (over a quadrant) is depicted here, sampled on a

256×256 regular grid. The finite set of samples introduces apparent patterns (*left*) which can sometimes be removed, or reduced, by specially designed reconstruction algorithms (*right*). Zoomed insets are shown in the *middle*

using three pixel colors (red, green, and blue); 3D geometry is commonly expressed as simplicial complexes (e.g., triangle meshes); fluid and other dynamical simulations are performed by propagating physical attributes at discrete locations. A fundamental advantage of discrete representation is that a finite set of data points, or samples, may be used to represent the function under consideration. The process of selection of the locations of these data points in the function domain is called sampling.

The distortion exhibited by the discrete function, due to an insufficient set of data points, is called aliasing. The practical elimination of this error, in general, is still considered an open problem. A thorough discussion of the fundamental problems related to sampling, reconstruction, and aliasing may be found in textbooks on signal processing [1]. The problem of anti-aliasing, or abating the distortion, has enjoyed much attention across several domains of computer graphics.

Images

The choice of a discrete grid, of pixels, to represent an image comes with a penalty – aliasing. If the underlying continuous image exhibits rapid spatial (or temporal) variation, unless the resolution of the spatial grid (resp. frame rate) is large enough, artifacts appear in the image as shown in

Fig. 2. To avoid aliasing, the sampling frequency must be twice the maximum Fourier frequency in the continuous image.

In the frequency domain, if there exists a finite frequency above which the Fourier amplitude spectrum of the image (before sampling) is zero, then aliasing can be avoided by suitably raising the number of samples on the grid. Such signals (images) are known as band limited, and this approach to anti-aliasing is called super-sampling. If the sampling rate is above twice the maximum frequency, then an ideal low-pass reconstruction filter [3] may be designed that is guaranteed to eliminate aliasing. The primary advantage of super-sampling is its simplicity and flexibility. It is widely used in rendering since it can be used in conjunction with complex primitives such as polygons, implicit functions, or parametric surfaces. Common strategies used to generate the sample locations include regular grid sampling, stratified random (jittered) sampling, and sample sets with blue-noise spectral characteristics.

If the underlying continuous signal contains positive energy at arbitrarily high frequencies or is not band limited, then no finite resolution of the discretization can eliminate aliasing. This is typical, since the existence of any step edge implies arbitrarily high frequencies. In such cases, anti-aliasing may be performed by first blurring, or

band limiting, by convolving with a smooth prefilter. Prefiltering is a way of enforcing the image signal before sampling to be band limited. Efficient prefiltered anti-aliasing is tricky for rendering: It involves continuous area integrals with detailed boundary information to find the integration limits; its applicability depends on the primitive. However, it is effectively used in texture mapping, when a high-resolution texture is available, and needs to be mapped on an object that potentially projects onto a small area in the image. Rather than mapping the high-resolution texture and then anti-aliasing at runtime, a popular approach is to query the appropriate level, based on the projected area, from a precomputed, prefiltered hierarchy of the texture. Since anti-aliasing is precomputed with this mip-mapping (multum-in-parvo-mapping) approach, it is widely used in real-time computer graphics applications such as rendering in video games.

Geometry

Polygon meshes are a popular choice for representing 3D geometry in computer graphics. They are simple and intuitive to manipulate locally, and they lend themselves to efficient rendering. Modeling or creating high-quality polygon meshes requires skilled artistry and sophisticated 3D modeling tools. To circumvent the long modeling process, artists often use 3D scans of objects as a starting point to their design. However, scanners today output point clouds as representations of underlying surfaces. The simplification and resembling of these point clouds are considered essential steps before the scanned model is usable for rendering or surface reconstruction.

Similar to the reconstruction of anti-aliased images, reconstruction of the underlying geometry from its point-sampled version is a challenging problem. The difficulty is exacerbated by the need to generalize elegant sampling theories that are applicable in Euclidean domains, such as for image processing, to arbitrary manifolds. Spectral analysis of manifolds is based on the eigenfunctions of the Laplace–Beltrami operator, just as Fourier analysis is based on trigonometric harmonics. The extension of signal processing on arbitrary

manifolds has inspired many useful algorithms for resampling point-sampled geometry, smoothing manifolds, reconstructing simplicial manifolds from point samples, etc. A comprehensive description of sampling and processing of polygonal meshes can be found in [2].

Plenoptic Functions

While rendering images with effects such as defocus (due to a finite camera aperture) and motion blur (due to a finite exposure), the radiance at each pixel is obtained by integrating estimates of incident radiance over the aperture and time. That is, at each pixel (x, y) on the image plane, radiance estimates along a direction (u, v) , so that the ray from the pixel passes through the aperture, and at times (t) are integrated.

The general rendering process involves reconstructing portions of the plenoptic function by estimating radiance at 5D sampled locations (x, y, u, v, t) . The radiance estimate at each sampled location is obtained via numerical integration in a high-dimensional space, accounting for different transport phenomena such as reflection, refraction, scattering in participating media, and occlusion. Hence, the cost of sampling the plenoptic function is high. Although the domain spans a higher-dimensional space, standard signal processing results are still directly applicable. The search for efficient reconstruction algorithms for the portions of the plenoptic function required for rendering has spawned a recent flurry of research. A recent trend in high-quality rendering is to develop ways of approximating frequency domain characteristics of the plenoptic function, using which adaptive sampling and reconstruction filters may be derived.

Physically Based Simulation

The goal of physically based simulation, in computer graphics, is to animate virtual objects by mimicking their physical interactions with the environment. The simulation may be of rigid bodies, deformable objects, or fluids. Although the discretization plays a critical role in deciding the quality – tractability, stability, or fidelity (realism) – of the simulation in all three cases, it is particularly important in fluid simulations.

The introduction of a non-penetration constraint in rigid body simulation introduces discontinuities in attributes such as position and velocities at the moment of collision. Thus, accurately identifying the moment of collision is important. Many methods have been proposed to perform collision detection, and they resort to different discretization [4] of the geometry and time domain.

Deformable objects are simulated using a number of techniques: mass-spring systems, the finite difference method, the finite element method, mesh-free methods, coupled particle systems, and reduced deformable models based on modal analysis. Each of these methods relies on a discretization of the geometry and time, and the choice of discretization has a significant effect on the stability, sensitivity, and fidelity (realism) of the simulation. The list of sampling schemes used in this context includes a cubic octree hierarchy, non-nested hierarchy of meshes (FEM), regular spatial grids (FDM), uniformly distributed samples, and samples with blue-noise spectral profiles. The interested reader is referred to [5, 6] for a survey of the methods.

The central problem in fluid simulation for computer graphics applications is the robust solution of the incompressible Navier–Stokes equations [7]. One of three strategies is popularly adopted to decide the locations where physical attributes such as pressure, viscosity, density, and velocity are iteratively computed at each time step. The first option is a regular grid over the spatial extent of the fluid and is an Eulerian approach to the problem. The second option is to represent the fluid using discrete particles that measure these attributes as the particles themselves are advected about. The third option is to use a combination of irregularly spaced samples and regular grid. As with reconstructing images and geometry, the sampling rate governs the largest frequency variation that can be faithfully reconstructed. Simply increasing the number of samples in a fluid simulation quickly results in prohibitively expensive computation times, and so adaptive sampling strategies are key to

practicable fluid simulation. Octree-based sampling, blue-noise sampling, and regular (grid) sampling are commonly used.

Statistical Sampling: Sampling for Estimation

Another application of sampling, in computer graphics, is to estimate the statistics of a function under consideration from values of the function at sampled locations. An estimator is a combination of the sampling strategy and the process of combining the samples. The fidelity of the mean and the variance of estimates produced by an estimator are both typical measures of quality for estimators. For example, a Monte Carlo estimator for the expected value of a function is the average of the function evaluated (sampled) at uniformly random locations in the domain. This simple estimator converges to the correct answer, in the limit of sampling the domain.

Physically based image synthesis involves estimation of a portion of the plenoptic function, or incident radiance at each (x, y, u, v, t) , where (x, y) is on the image plane. The problem is addressed by sampling at two levels: designing a high-level rendering strategy or estimator and then choosing low-level, specific sampling strategies.

The rendering strategy governs how light paths are sampled. For example, in path tracing, each estimate of the radiance is obtained by sampling the contribution of a single path from the space of light paths originating at (x, y) on the image plane and terminating at a light. In distributed ray tracing, incident radiance is recursively estimated at each bounce, using multiple incident samples. Metropolis light transport adopts a Markov-chain model to sample in path space, given a pool of initial paths using which the search is seeded. The specific sampling strategy defines how samples are generated. For example, at each bounce (whether path tracing or distributed ray tracing), the outgoing directions may be generated using quasi-Monte Carlo, random, stratified, or importance sampling schemes [8].

Error and Assessment

The graphics literature is rich with numerous sampling algorithms. Ideally, the invention of a core sampling algorithm develops in four stages: motivation for a novel algorithm, the design of the sampling procedure or algorithm, analysis of the proposed algorithm, and finally assessment of the resulting samples. This section describes typical approaches for the latter two stages – and assessment. The motivation and design of specific sampling algorithms are closely tied to the specific application and beyond the scope of this article.

Sampling for Reconstruction

The analysis of sampling algorithms (for reconstruction) is typically performed in the frequency domain. Fourier analysis is typical for Euclidean domains such as images and 4D plenoptic functions. For frequency analysis over spherical domains and spaces of rotations, spherical harmonics are the popular choice in computer graphics. Using the eigenfunctions of the Laplace–Beltrami operator as a frequency basis is gaining popularity for frequency analysis on arbitrary manifolds. Regardless of the choice of frequency bases, the sampling theorem from signal processing is a fundamental test to analyze the sufficiency of sampling. However, most frequency domain analyses are global. For example, it is impossible to use the Fourier transform of an image to predict local regions with high (or low) variation. A typical trick for improving local analysis is to use windowed transforms. However, any gain in localization due to windowing is at the cost of precision in the frequency domain, in accordance with the uncertainty principle.

The assessment of reconstruction error is domain specific. Generic measures such as root mean squared error or peak signal to noise ratio, although common, are typically insufficient. For example, the “quality” of reconstructed images relies heavily on human perception. Although many studies have been performed in this area, automatic assessment of reconstructed images,

including perceptual considerations, is still an open problem. For 3D geometry, the problem of automatic assessment of final appearance is compounded by its dependence on view and shading.

Sampling for Estimation

The typical measures for the assessment of estimators are accuracy (bias) and precision (variance). Bias measures the expected discrepancy between the estimated value and the actual value. Variance measures the spread of predicted values. Bias and variance are difficult to attain simultaneously. Estimators typically strike a trade-off between the two, and their relative importance depends on the application.

Despite the quantifiable measures of bias and variance, automatic assessment of estimators is not prevalent in image synthesis. Bias leads to physically inaccurate images while variance manifests as noise across the pixels. A large bias is generally believed to be less objectionable (perceptually) than a large variance. Variance reduction schemes such as stratified sampling, importance sampling, control variates, and anti-thetic variates are commonly used in Monte Carlo rendering. The resulting estimators are typically compared by manual inspection of their resulting images given a particular virtual scene. Images are generated with increasing numbers of samples and the estimator with the least noise is considered best. In addition, a converged image using an unknown estimator is visually compared against a reference solution (with a known estimator and a large number of samples). Clearly, such comparisons are not general and only valid on the particular images that the methods are demonstrated on. The development of an automatic method for such assessment is an open problem.

Sampling, Reconstruction, Aliasing, and Anti-aliasing

Erik Reinhard

InterDigital, Cesson-Sévigné, France

Definition

In computer graphics (as well as other disciplines), antialiasing refers to a collection of techniques to reduce the effects of aliasing. When a continuous signal or image is sampled, or a digital image is resampled, the sampling imposes a limit on the frequencies available in the input signal that can be represented in the resulting output signal. Frequencies higher than this limit (the Nyquist frequency) are mapped to lower frequencies, a process known as aliasing. In images this will be visible as objectionable artifacts. Removal of unrepresentable frequencies through low-pass filtering prior to sampling is a common anti-aliasing technique.

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 1 A function containing a range of frequencies

Key Principles

A function or a signal (including images and video) typically contain oscillations at various different frequencies. A one-dimensional example is shown in Fig. 1, where from left to right the frequencies increase. For those interested in reproducing the figures shown in this article, the function displayed in Fig. 1 is given by $f(x) = (1/2) \cos(0.8\pi(x + 1)^{x/15}) \sin((\pi/40)(0.6x + 3)^{2.1})((20 - x)/20)^{0.4} + 0.05$.

Such a function can be represented digitally by sampling it. However, sampling causes a loss of information, whereby the high frequencies are lost. These are mapped (or aliased) to lower frequencies. See more on this in the “Sampling” section below.

To turn the samples back into a function, to the extent possible, a reconstruction method can be applied. This is often achieved with the aid of a filtering procedure. The filtering ensures that unrepresentable portions of the signal are removed, and thus reduce aliasing problems. Filtering can therefore be seen as an anti-aliasing method. How to achieve anti-aliasing during reconstruction is discussed in the “Reconstruction” section below. Reconstruction, for example, by filtering, is used in displays when images are displayed, but can also be performed to achieve various tasks, such as downsampling (reducing

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 2 The single-sided (left) and double-sided amplitude spectrum (right) of the function of Fig. 1

the resolution of an image) or upsampling (increasing the resolution of an image).

Filtering can also be applied to a function prior to sampling, to remove frequencies that cannot be represented by the sampled signal. This may help to reduce the effects of aliasing during reconstruction.

Sampling

A useful method to help understand the causes of aliasing is by Fourier analysis. In particular, the amplitude spectrum gives insight. The amplitude spectrum of the example function in Fig. 1 is shown in Fig. 2. The single-sided amplitude spectrum is shown on the left in this figure, and the double-sided amplitude spectrum is shown on the right. The peak of the amplitude spectrum is located at a frequency of 0 Hz. Higher frequencies are represented less. In this example, the highest frequencies are less than ten cycles per pixel (10 Hz).

The example function of Fig. 1 is now sampled. In the spatial domain, sampling is equivalent to applying the element-wise product (or Hadamard product) of the function with a comb function. The latter is a sequence of spikes placed at the sampling locations, as shown in Fig. 3 (left). The samples are placed such that

there are four samples per unit on the x -axis. Thus, the sampling is carried out at a frequency of 4 Hz. The result of sampling is shown in Fig. 3 (right). It can be seen in this figure that the slowly varying part of the function on the left is well represented by the samples, whereas the high frequencies on the right are not well represented.

The process of sampling can be analyzed in the Fourier domain. The Fourier transform of a comb function is a comb function, as shown in Fig. 4 (left). The spikes are spaced at a rate of 4 Hz, which is consistent with the sample spacing of four samples per unit in Fig. 3.

An element-wise multiplication in the spatial domain becomes a convolution in the Fourier domain. Thus, the Fourier transform of the signal (Fig. 2, right) is convolved with the Fourier domain comb function of Fig. 4 (left). This has the effect of replicating the amplitude spectrum of the function with offsets in multiples of 4 Hz, as shown in Fig. 4 (right).

The loss of information as a result of sampling comes from the fact that higher frequencies of the central copy overlap with the replicated copies. Likewise, the high-frequency tails of the replicated copies overlap with the low-frequency part of the central copy. This means that high-frequency content is misrepresented, and occurs in the sampled signal as low frequencies. The mapping of high

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 3 A comb function in the spatial domain (left). Sampling of the function of Fig. 1 is achieved by

element-wise multiplication of the function with the comb, leading to the sampled signal shown on the right

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 4 The Fourier transform of a comb function is a comb function (left). In the Fourier domain,

sampling is equivalent to convolving this comb with the Fourier transform of the function (see Fig. 2). The result of this convolution is shown on the right

frequencies to low frequencies as a consequence of sampling is called aliasing.

At a sampling rate of four samples per unit, the spikes in the Fourier domain are spaced at 4 Hz intervals. This means that the central copy of the sampled signal in the Fourier domain is reasonably well represented between -2 and $+2$ Hz, as can be seen in Fig. 4 (right). The highest representable frequency is therefore half of the sampling frequency. This limit is known as the Nyquist frequency.

Note, however, that the high-frequency tails of the replicated copies also overlap with the low frequencies of the central lobe, so that minor distortions of the low-frequency part of the signal can be expected.

If the function were sampled at a higher rate, then the spatial comb function of Fig. 3 would have its spikes placed more closely together. The corresponding Fourier domain comb function would have its spikes placed further apart. This would mean that the replicated copies of the signal

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 5 Ideal reconstruction in the Fourier domain involves a box function (left). Fourier domain reconstruction requires an element-wise multiplication of the sampled signal with such a box function. The box has

retained the central copy of the repeated pattern seen in Fig. 4, retaining all the frequencies that well represented in the sampled signal, and removing all the frequencies above the Nyquist frequency. This is theoretically optimal and leads to the reconstruction shown in Fig. 6

would see less overlap, and therefore higher frequencies could be represented. To ensure no overlap, the sampling frequency should be at least twice the signal frequency. In that case, the sampled signal would accurately represent the function. In the example, this would mean at least ten samples per unit, or a sampling frequency of 10 Hz.

For images, this solution could for instance involve taking more than one sample per pixel, and averaging these samples would produce a pixel value that is more representative of the function over the area that is covered by the pixel.

Increasing the sampling rate is of course a data-intensive method to limit the destructive effects of sampling. Instead, one might sample the function not at regular intervals but at random positions. In such a stochastic sampling scheme, regular aliasing patterns will be replaced by noise which is less objectionable to the human eye. A good distribution for stochastic sampling would be the Poisson disk distribution, as this guarantees a minimum distance between any pair of samples [1]. Jittered sampling first creates a regular grid, and within each grid cell a sample is placed randomly. Other random sampling strategies include N-rooks sampling and multijittered sampling [2].

Reconstruction

In the Fourier domain representation, reconstructing the original function from the sampled signal would require the disentanglement of the central copy from the replicated copies. Given a sampling rate and associated Nyquist frequency, separating the well-represented frequencies from the ill-represented frequencies would require removing all replicated copies, leaving only the central copy. Noting that overlapping parts of the various copies cannot be disentangled, the optimal way of separating the central copy from the replicated copies in the Fourier domain is to apply a box function (Fig. 5, left), i.e., by element-wise multiplication. The result of this procedure is shown in Fig. 5 (right). Note that in this example only frequencies up to 2 Hz are retained, which is consistent with the original sampling rate of four samples per unit.

After applying an inverse Fourier transform to the result of Fig. 5 (left), the result is the reconstructed signal shown in Fig. 6. The same result could have been obtained by convolving the sampled signal with a sinc function directly in the spatial domain. Note that the low frequencies are generally reconstructed with good accuracy. The

Sampling, Reconstruction, Aliasing, and Anti-aliasing,

Fig. 6 The reconstruction results in the spatial domain of the Fourier domain reconstruction shown in Fig. 5. It is equivalent to convolution of the sampled signal with a sinc filter in the spatial domain

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 7 For computational reasons, a function is often reconstructed by convolving with a box function (left) in the spatial domain. The reconstructed result is shown on the right

high frequencies on the right, however, have not been recovered, as they have simply been truncated.

While this approach to reconstruction is optimal, as there are currently no better ways to separate representable frequencies from unrepresentable ones, the disadvantage is that this is a computationally expensive way to reconstruct a signal. While application of the box filter in the Fourier domain is not particularly expensive to compute, it requires the signal to be transformed to and from the Fourier domain, which dependent on use case may be prohibitively expensive.

Applying the convolution with a sinc filter in the spatial domain is also computationally expensive, because of the infinite extent of the sinc filter.

As a result, in practice, a variety of simpler reconstruction filters are used, with which the sampled signal is convolved in the spatial domain. Such anti-aliasing filters are discussed next.

Anti-Aliasing

Perhaps the simplest reconstruction filter is a box filter with which the sampled signal is convolved in the spatial domain. While this is the simplest of

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 8 The Fourier transform of a box function is a sinc function (left). Reconstruction with a box in the

spatial domain is equivalent to multiplication with a sinc function in the Fourier domain, as shown on the right. Compare with the two-sided amplitude spectrum of Fig. 2

the reconstruction filters, it also has the lowest quality, leading to potentially visible artifacts. Due to its simplicity, it is, however, used often.

An example of a box filter is shown in Fig. 7 (left), and the result of the reconstruction with this filter is shown in Fig. 7 (right). It can be seen here that the filter leads to noticeable steps.

The cause of this problem can be seen through Fourier analysis. The spatial box function becomes a Fourier domain sinc function, as shown in Fig. 8 (left). An element-wise multiplication of a sinc with the amplitude spectrum of Fig. 4 (right) results in the amplitude spectrum shown in Fig. 8 (right). Here, the central copy has been retained, but so have many high frequencies above 2 Hz that should have been removed.

Other reconstruction filters aim to provide a better trade-off between computability and accuracy. In essence, their quality depends on how well they approximate the sinc function. Simple approximations are tent filters, cubic splines [3], cubic convolution interpolation [4], and Gaussian filters.

In particular, the Lanczos family of filters provides a reasonable balance [5, 6]. The Lanczos filter is defined as a windowed sinc function, whereby the central portion of the sinc is retained. The filter family has a single parameter which

defines how much of the central portion is retained, counted in number of (side-)lobes. Thus, a Lanczos (2) filter consists of the central lobe of a sinc as well as one side-lobe to each side. A Lanczos (3) filter includes two side lobes on each side, while a Lanczos(n) filter includes ($n - 1$) side-lobes. Examples of such filters, along with their reconstruction results, are shown in Fig. 9. As can be seen in this figure, incorporating more side-lobes provides a higher accuracy. However, the spatial convolution becomes more computationally expensive because the size of the filter kernel increases.

Image Downsampling

The theory explained above is routinely applied to images. To see the visual effect of a variety of reconstruction filters, an input image was downsampled by a factor of 8 using several reconstruction filters (nearest neighbor, bicubic, lanczos (2), lanczos (3), and box). The resulting images were then upsampled by a factor of 8 using pixel replication to arrive at the original size. The input image was chosen to be a quarter of HD size (which is 1920×1080), so that when reproduced in this document at 300 DPI, the horizontal size is 3.2 inches ($1920/2/300 = 3.2$). The images in

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 9 Lanczos reconstruction filter kernels (left), and their reconstruction results (right). Top to

bottom: Lanczos kernels with parameters 2, 3, and 9 were used, leading to an increasingly accurate (but computationally expensive) signal reconstruction

Fig. 10 are therefore reproduced at 300 DPI at 3.2 inches width to avoid the typesetting software performing additional resampling.

In Fig. 10, the images were downsampled in RGB space to show the effect of various reconstruction filters. Other color spaces may be

Sampling, Reconstruction, Aliasing, and Anti-aliasing, Fig. 10 Image downsampling by a factor of 8 using various reconstruction filters

appropriate for certain tasks. For example, color spaces that separate luminance from chrominance can be used to great advantage by exploiting the fact that human vision is less sensitive to errors in chrominance than it is to errors in luminance. Using the same downsampling and upsampling procedure outlined above, Fig. 11 shows an image processed in RGB space. Here the three color channels are treated identically (as in Fig. 10), showing a significant degradation of the image as a result of the sampling. Figure 11 also shows an image processed in YCbCr color space. The color space decomposes the image in a

luminance channel and two chromatic channels. The two chromatic channels were downsampled by a factor of 8 and then for the purpose of visualization upsampled to its original size by pixel replication.

Schrödinger, Erwin

Michael H. Brill¹ and Rolf G. Kuehni²

¹Lawrenceville, NJ, USA

²Charlotte, NC, USA

Erwin Schrödinger (1887–1961) was born in Erdberg, Austria, to a father of Austrian and a mother of mixed Austrian-English descent. He

Schrödinger, Erwin,
Fig. 1 Schrödinger's
 portrait on the Austrian
 1000-Schilling note

studied physics in Vienna under Franz Exner and became his assistant in 1911. He was influenced early by the writings of the German philosopher Arthur Schopenhauer resulting, among other things, in his interest in color theory. Three of his papers on color were written in Vienna after he concluded his military service in 1918 and before assuming a position at the University of Zürich in 1921. There he published six more papers on color and vision. His interest in color, which did not extend beyond his years in Zürich, apparently was due to his deep involvement with the works of Schopenhauer who in turn was influenced by Goethe.

In Zurich, Schrödinger did his most important work, on quantum wave mechanics, for which he shared with Paul Dirac the 1933 Nobel Prize in physics. In 1940, Schrödinger moved to Ireland, where he remained until his retirement in 1955. Then he returned to Vienna. Among his achievements is the thought experiment known as Schrödinger's Cat.

Schrödinger's contributions to color include the following:

- (a) He offered the first mathematical proof [1] of the theorem sketched by Wilhelm Ostwald that, under any illuminant, the object-color tristimulus locus is contained by a two-dimensional manifold generated by reflectances that are 1 or 0 at each wavelength and with at most two transitions between 0 and 1. Robert Luther later called these reflectances "optimal colors." The maximality of two transitions depends on the convexity of the

spectrum locus, as is clear in his very brief proof: "*If a pigment has three transition points that in the chromaticity diagram are not located on a straight line, by moving the transition points its reflectance can be changed in a manner that results in a lighter pigment of the same chromaticity coordinates. Therefore, it cannot be optimal.*"

- (b) He was the first to use differential geometry for color space, to import brightness as one of the space's coordinates, and to infer total color difference (in units of just-noticeable differences) through arclength along geodesics [2, 3].
- (c) He was the first to offer a mathematically detailed connection of the Young-Helmholtz three-color theory and Hering's opponent-color theory [4], after Helmholtz offered such a concept in 1896 and von Kries that of a zone theory in 1905.

In addition to this work, Schrödinger also published several other works relating to color science [5–9].

Besides Isaac Newton, we are unaware of any color scientist other than Schrödinger whose portrait appeared on paper money (Fig. 1). (Goethe satirized paper money [*Faust*, Part 2, Act I, Scene 4], but did not appear on it.).

characterized by unilateral, throbbing, and moderate-to-severe headache lasting 4–72 h, typically accompanied by nausea and photophobia and phonophobia [2]. In approximately 20% of patients, the migraine can also be preceded by transient neurological symptoms (aura) that usually develop gradually over >5 min and last for <60 min. Auras are most frequently visual (>90%), but may also involve other sensory symptoms (pins and needles, numbness), hemiparesis or speech deficits. Visual symptom (aura) often has a bimodal progression with positive symptom (**scintillating**) followed by negative symptom (**scotoma**). To date, the trigger mechanisms of migraine with aura are cortical spreading depression (CSD). Migraine with aura (MWA) is diagnosed according to the operational diagnostic criteria of The International Classification of Headache Disorders third edition [2]. Although, in migraine with aura, headache which fulfills the same features as migraine without aura (MWOA) frequently occurs following the aura, there are also cases in which, along with aging, there is no headache that fulfills the features of MWOA, or in which there is only the aura but no headache [3]. Population-based studies indicate that a diagnosis of migraine with aura is associated with an increased risk of comorbidities [patent foramen ovale [4], stroke [5], restless legs syndrome [6]].

Overview

The patterns of the visual aura are diverse, but scintillating scotoma is representative. Scintillation is a positive symptom in which light is seen despite the lack of any input visual stimulus, and scotoma is the negative symptom in which an input visual stimulus, in the same locus as the scintillation after it has disappeared, is not visible for some time. The phenomenon of the extension of these positive (scintillation) and negative (scotoma) symptoms within the visual field is presumed to be in correspondence with changes in neural activity in the occipital lobe. It is understood that these changes in neural activity are a phenomenon known as cortical spreading

Scintillating Scotoma, Fig. 1 The analytical drawings of the spatiotemporal evolution of spreading migraine hallucinations. Left: a scintillating scotoma, spreading at the intervals shown. The blind spot is shown as the dotted circle, and the fixation point as x; alternate outlines are solid and dotted to avoid confusion; scintillations were

confined to the region above the line s-s. Right: successive forms of a scintillating scotoma, mapped at different time intervals as indicated; the fixation point is shown as x. From Lashley [7]. Copyright © 1941 American Medical Association. All rights reserved

depression (CSD). CSD is a wavelike, self-propagating phenomenon of neuronal depolarization, which originates in the cerebral cortex (2–6 mm/min), as well as of inhibition of neuronal activity.

Lashley made a detailed study of his own scintillating scotoma, calculated the speed of migration of the scintillating scotoma in the visual field, and showed that it migrates at approximately 3 mm/min in the visual cortex of the occipital lobe [7] (Fig. 1).

With CSD in an experimental rabbit model, a transient inhibition of neural activity is observed upon electrical stimulation of the cerebrum, which recovers to the state of normal spontaneous activity after a certain period of time [8]. Also, when records were made by an array of recording electrodes on the cerebral surface of a rabbit, a phenomenon was observed in which transient inhibition of cerebral activity was sequentially propagated after electrical stimulation. The speed of propagation of CSD in the experimental rabbit model and the speed of propagation of the scintillating scotoma reported by Lashley were similar, both having been found to be approximately 3 mm/min. The electrophysiological

characteristics of CSD which have been indicated include (1) CSD occurs under specific conditions, (2) its extension is autonomous, (3) the speed of extension is 3 mm/min, (4) inhibition of each locus is sustained for 1–3 min, with a total refractory period longer than 1 min, and (5) all intrinsic/induced neural activities are inhibited [9].

The first evidence for the CSD hypothesis of migraine in the human cerebrum was a study conducted of regional cerebral blood flow (rCBF) in the aura phase using Xe-CT, in which spreading oligemia originating in the occipital lobe, similar to CSD, was observed [10]. The oligemia preceding hyperemia is similar to the hemodynamics, which is observed in experimental CSD. Woods et al. observed, by positron emission tomography of cases in which migraine arose accompanied by abnormal vision, spreading hypoperfusion in which, together with the onset of an episode, an area of reduced rCBF gradually extended forward from the bilateral occipital lobe [11]. The best-known report related to this is that of Hadjikhani et al. [12]. In one of the three patients, it was possible to start the test before the onset of aura since an episode was induced with near certainty upon engaging in basketball

Scintillating Scotoma, Fig. 2 Spreading suppression of cortical activity during migraine aura, as shown by functional MRI. **(a)** A drawing of the progression over 20 min of the scintillating field defect, as described by the patient. **(b)** The spread of the signal from the posterior pole towards more anterior regions representing the peripheral visual field; MR perturbations develop earlier in the foveal regions than in the periphery, consistent with the

progression of the aura from the center to the periphery. **(c)** The MR maps of retinotopic eccentricity acquired during interictal scans. As shown in the logo in the upper left, voxels that show retinotopically specific activation in the fovea are coded in red. Parafoveal eccentricities are shown in blue, and more peripheral eccentricities are shown in green. From Hadjikhani et al. [12] Copyright 2001 National Academy of Sciences, U.S.A.

practice. Upon functional MRI with presentation of visual stimulus, the signal in the visual cortex became unresponsive to stimuli as the aura began and the baseline signal slowly increased at the same time. This originated in the V3a area, extended with a speed of 3.5 mm per min to the adjacent occipital cortex including the primary and secondary visual cortices, and also coincided with the areas of the visual aura in the visual field. Subsequently, the cerebral response to visual stimuli remained weak over more than 15 min and the baseline diminished gradually to become lower than before the episode (Fig. 2).

The transient rise in this signal was similar to the change in blood flow, which was observed in accompaniment to CSD in the experimental model. This report was evidence in support of the view that the phenomenon of CSD is involved in the pathology of scintillating scotoma in migraine.

Simultaneous Color Contrast

A. Soranzo
 Faculty of Development and Society,
 The Department of Psychology, Sociology and
 Politics, Sheffield Hallam University,
 Sheffield, UK

Definition

Simultaneous color contrast is the condition whereby two surfaces with the same spectral composition are perceived to have a different color when they are placed against different surrounds with different chromaticity (see Fig. 1).

Simultaneous Color Contrast, Fig. 1

The spectral components of the squares in the centers of the red and yellow surrounds are the same. The appearance of the color is different, however. The two squares appear to acquire the opposite spectral component of their surrounds

Simultaneous Color Contrast, Fig. 2

The gray squares in the centers of the white and black surrounds are the same. The appearance is different, however: the square to the left appears darker than the square to the right

History and Theories

The term “simultaneous” was introduced by Chevreul to “distinguish this phenomenon to the ‘successive’ contrast, where two colors appear in succession upon the same retinal area” [1, p. 264].

The term “contrast” indicates that the perceived color of the surfaces is “contrasted” by the color of the surround. As this term is also used in the literature to specify the relative intensity of the stimulation, some authors prefer the term “induction” over contrast.

When the surrounded and surrounding areas are achromatic, this phenomenon is named simultaneous brightness (or lightness) contrast (see Fig. 2).

This is one of the most studied phenomena in visual perception and has been the focus of centuries of debate that has interested scientists and philosophers since Aristotle’s time [2]. In the

nineteenth century controversy raged between Hering [3], who supported an explanation based on retinal neuron interaction processes, and Helmholtz [1], who was in favor of an explanation based on higher level processes, involving assumptions about the configuration as a whole.

The retinal-based interpretation (also referred to as the “low-level” interpretation) was particularly in vogue during the 1960s mainly because of the physiological discovery of the lateral inhibition process in the limulus retina [4]. To explain the contrast phenomenon the retinal-based interpretation focuses on the notion that the receptors that are stimulated by the surround then send inhibition to the receptors that are stimulated by the surrounded area. According to this view, the simultaneous color contrast shown in Fig. 1 occurs because the receptors stimulated by the red surround inhibit the red sensitive receptors

stimulated by the orange square, leading to a yellowish appearance. Conversely, the receptors stimulated by the yellow surround inhibit the yellow sensitive receptors stimulated by the orange square, leading to a reddish appearance.

A similar explanation is provided for the contrast phenomenon seen in Fig. 2. The receptors stimulated by the light surround send inhibition to the receptors stimulated by the surrounded square causing perceptual darkening. On the other hand, the receptors stimulated by the dark surround send little inhibition to nearby receptors and, therefore, there is no darkening effect [5].

During the last few decades, however, the balance has been shifted toward more high-level theories. This is because a series of phenomena have been presented that are difficult to explain on the basis of retinal interactions. One of the best-known demonstrations is the Benary cross (see Fig. 3), discovered by Max Wertheimer and studied further by Benary [6].

Although both gray triangles are surrounded by the same amount of black and white, the left triangle appears lighter than the right triangle. Even more appealing is the contrast phenomenon found by Agostini and Galmonte [7]. In this case, a gray region surrounded by a dark area appears darker than an identical gray region surrounded by a light area (see Fig. 4).

The interested reader can find more of these effects elsewhere [8–12]. As these examples are difficult to be explained on the basis of retinal interactions, they have been interpreted according to the principles of perceptual organization [13, 14]; that is, the perceived color of a surface is determined primarily by the global contrast between the surface and the color of the surfaces to which it perceptually belongs (where perceptual belongingness refers to the grouping of a set of apparent elements into a perceived whole).

The low-level explanation has not, however, been completely abandoned as some contrast phenomena seem to involve retinal interactions such as those that generated by gradual luminance transitions (for example, [15–18]). Figure 5 shows a paradoxical contrast effect generated by

Simultaneous Color Contrast, Fig. 3 The Benary cross. The two gray triangles are the same. Although they are surrounded by the same amount of white and black area, the left triangle appears lighter than the right triangle

luminance transitions. The luminance surrounding the two little squares to the left side is the same, but the top square looks darker. Similarly, the luminance surrounding the two little squares to the right side of Fig. 5 is the same, but the top one looks lighter. Authors named this phenomenon the “phantom illusion” [19] because it is generated by imperceptible luminance gradients, which profile is represented next to each display.

Besides the debate between low- and high-level supporters, a vivid debate exists among scientists asserting that the retinal image is decomposed by high-level mechanisms. This is the debate between the *framework* and the *layer* types of decomposition models [27].

The framework model maintains that the visual system, in agreement with the belongingness principles, processes the light reflected by surfaces that reaches the eyes by grouping it into a set of contiguous frameworks. According to this model, contrast effects are generated by the geometric and photometric relationships among the surfaces within the same perceptual group, that is, within the same framework [14, 20].

Simultaneous Color Contrast, Fig. 4

The dashed elements of the cubes are the same gray but those to the left appear darker than those to the right despite of the fact that they are surrounded by a darker area

Simultaneous Color Contrast, Fig. 5

The phantom illusion. Wide unnoticeable luminance transitions generate contrast effects on the surrounded targets (top). Narrow unnoticeable luminance transitions generate assimilation (bottom)

Conversely, the *layer* model claims that the visual system operates by splitting the light reaching the eyes into separate overlapping layers which correspond to separate physical contributions (illumination, reflectance, transparency, etc.). According to this model, contrast effects are generated when the light reaching the eyes is misattributed to the surface color and illumination. In other words, part of the light that the visual system should attribute to the surface color is instead attributed to the illumination or vice-versa [21–29].

To disentangle these two models Soranzo, Lugin, and Wilson [30] studied the contrast

phenomenon in the Virtual Reality Cave. This apparatus permitted the manipulation of the geometrical relationships between the surfaces while maintaining the same photometric relationships (i.e., the amount of light reaching the observers' eyes remained constant). However, findings indicated that both of the decomposition processes which the framework and the layer models advocate are *jointly* accountable for the color contrast phenomenon. The color contrast phenomenon may therefore be attributed to the summative effect of the framework and the layer processes.

[Sleep model](#)

Definition

Nighttime sleep and daytime alertness and performance are affected by daytime light through a circadian route and through a direct photobiological route.

Sleep, Health, Alertness, and Performance

Just as air, food, and water, sleep is a prime requirement for life. It saves bodily energy by slowing down many processes, and it has a restorative function. It is well established that insufficient sleep and sleep of low quality relates to all-cause mortality [1–4]. Health problems such as obesity, diabetes, cardiovascular diseases, and depressive disorders can be linked with insufficient sleep or bad sleep quality [5–7]. Sleep also plays a role in storing new information into our long-term memory [8]. The restorative function of sleep is not only fundamental for our health; it is also needed for adequate alertness and performance during the time that we don't sleep.

Model of How Sleep Is Regulated

In the early 1980s of the last century, cooperation between the universities of Zurich, Basel (Switzerland), and Groningen (the Netherlands) has resulted in a classical model of how sleep is regulated [9, 10]. It is still today the prevalent one [11]. The model is based on an interaction of two

different processes: a homeostatic and a circadian one. Homeostasis is a process that opposes changes. The homeostatic process in sleep-wake regulation increases sleep pressure (fatigue) after waking up and decreasing it during sleep. It is referred to as process S. Sleep pressure is behavior-dependent, namely, of the time being awake and of the previous sleep history. Sleep can occur when the circadian process (called process C) provides conditions for sleep. Process C is not behavior-dependent but dependent on the state of the body regarding, for example, melatonin and cortisol levels and body temperature. The amount and timing of light and dark influence circadian processes and thus also the sleep process C.

Figure 1 (top) shows an example of the typical exponential increasing sleep pressure after waking up together with the steeper, and again exponential, declining sleep pressure during sleep. Figure 1 (bottom) shows an example of the circadian curve where point A represents a situation where the conditions are such that sleep is possible and, further in time, point B where the conditions make sleep again difficult. The time frame between A and B represents the sleep window.

The model is a simplification of complicated behavior and bodily processes of which still much is unknown. A physiological confirmation of the homeostatic process has not yet been identified. Nevertheless, the model permits for the prediction of effects of sleep-wake scenarios and ratings of sleepiness, alertness, and performance [12, 13].

Daytime Light and the Circadian Process

Because the free-running rhythm of the circadian process, controlled by our biological clock (suprachiasmatic nucleus), is with most people different from the 24-h solar day, external cues which have an exact 24-h rhythm have to synchronize our biological clock with the 24-h rhythm. Under normal situations, the natural 24-h dark-light rhythm synchronizes the free-running rhythm with the 24-h rhythm. In chronobiology, the word “zeitgeber” has become an usual expression, also in English-language literature, for this “time-giver” effect of the transition of

Sleep, Alertness, and Light, Fig. 1 Two-process model of sleep regulation. Homeostatic process S drives sleep pressure (increasing after awakening and decreasing during sleep). Process C, the circadian process, provides the bodily conditions for sleep between points A and B: the sleep window

Sleep, Alertness, and Light, Fig. 2 Subjective nighttime sleep quality as a function of the average daytime vertical illuminance during work hours at the working place. Electrical lighting used 3000 and 4000 K fluorescent tubes [21]

dark and light. Especially morning light is a powerful zeitgeber.

Sufficient light during daytime and good darkness during nighttime is, therefore, a prerequisite for a sufficient nighttime sleep of good quality. A recent study with 20 test persons showed that light exposure measured throughout the 24 h preceding the sleep period correlates with the objective sleep quality [14]. This study made, for the first time, use of a novel, mobile PSG unit. It was combined with an action watch with a light sensor. Light levels varied roughly between 10 lux and 30.000 lux. The results of this investigation suggest not only a fundamental influence of light exposure on the circadian aspect of sleep but also an influence of light exposure on the

homeostatic sleep pressure aspect. As the authors of this study state: “It could change the current understanding of the regulation of sleep.” A clear relationship was found between daytime lighting and subsequent, objectively measured, nighttime sleep quality.

Light Level

Different studies carried out under interior daytime-lighting conditions in working interiors have shown that lighting levels that fulfil the requirements for visual performance and satisfaction do often not fulfil the requirements for sleep [15–20]. A study of Aries [21] illustrates this convincingly. She studied the relationship between vertical illuminance at the eye during

daytime and the subsequent nighttime sleep quality of 42 office workers in April and May in the Netherlands. She recorded the average vertical illuminance, from daylight and electrical light, during daytime working hours at the workstations of these office workers, spread over ten different office buildings. She determined the subjective sleep quality of each test person over the test period using the Groningen Sleep Quality Scale

Sleep, Alertness, and Light, Table 1 Illuminances at the eye corresponding to a circadian stimulus value CS = 0.3 for different light [20]

Light source	Illuminance (lux) corresponding to CS = 0.3
Daylight D65	175
White phosphor LED 6500 K	170
White phosphor LED 3500 K	400

Sleep, Alertness, and Light, Fig. 3 The two routes through which daytime light may influence daytime alertness and performance

questionnaire. The results, given in Fig. 2, show that lighting during daytime correlates positively with nighttime sleep quality.

Figure 2 shows that the midpoint of the sleep quality scale corresponds to a value of 400 lux vertical illuminance: the bare minimum required for acceptable sleep quality. With the kind of light distributions, layout of luminaires typically used for office lighting, and correlated color temperatures between 3000 K and 4000 K, the average horizontal illuminance at working plane level corresponds to roughly three times the amount of vertical illuminance at eye height. A vertical illuminance of 400 lux thus corresponds to some 1200 lux horizontally, distinctly more than the values required today in most lighting standards for interior lighting for workplaces.

Light Spectrum

The studies discussed so far used the photopic illuminance as a parameter. Therefore, these

studies do not include the effects of the spectrum of the light. Figueiro [20] used the measure circadian stimulus (CS) as a parameter that includes the effect of the spectrum (see also the entry “Non-Visual Lighting Effects and Their Impact on Health and Well-Being” in this encyclopedia). For guidance of the practical meaning of a CS value of 0.3, the minimum required according to Figueiro, Table 1 gives the corresponding illuminance values at the eye for different light sources. With the light sources of today in interiors used for work (correlated color temperature around 3000–4000 K), the minimum requirement for morning light is at least 400 lux (at the eye). With light sources with CCT values of around 6500 K, this value can be considerably lower, down to slightly less than 50%.

Light, Sleep, Alertness, and Performance

Light affects sleepiness, alertness, and performance during daytime through two different routes (Fig. 3). Route 1 represents the circadian route and route 2 the direct photobiological one. Route 1 starts at the moment of daytime light on the previous day (“yesterday”). Daytime alertness and performance will obviously be better after a night with sufficient sleep of good quality. Daytime light of yesterday affects the nighttime sleep quality of yesterday. Therefore, the daytime lighting of yesterday influences sleepiness, alertness, and performance of today. Route 1 concerns long-term effects of light and lighting on circadian rhythms. Light received up to a few days before can cause these effects. Light can, however, also have short-term, direct effects within a short time after being exposed to light. These effects are called “direct photobiological effects.” These effects usually disappear shortly after the light exposure stops. An important example of a direct photobiological effect is light, both at day and night, acutely decreasing sleepiness and improving alertness [22–24]. The increase of alertness, in turn, has positive consequences for performance. Route 2, the direct photobiological route, concerns daytime light that invokes an acute

activating effect because of direct photobiological processes.

Spectral Luminous Efficiency

János Schanda
 Veszprém, Hungary

Synonyms

[Eye sensitivity functions](#); [Luminous efficiency function](#); [Relative visibility function](#); $V(\lambda)$, $V'(\lambda)$

Definition

Spectral luminous efficiency (of a monochromatic radiation of wavelength λ) [$V(\lambda)$ for photopic vision; $V'(\lambda)$ for scotopic vision] (see CIE e-ILV [1]).

János Schanda: Deceased

Ratio of the radiant flux at wavelength λ_m to that at wavelength λ such that both produce equally intense luminous sensations under specified photometric conditions and λ_m is chosen so that the maximum value of this ratio is equal to 1.

Unit: 1

Overview

By the end of the nineteenth century, photometry achieved a level where it became necessary to describe the light perception efficiency of radiation of different wavelengths. Several methods were used to determine the spectral luminous efficiency function (called also spectral visibility). The two most important ones were direct comparison and the flicker method (based on the fact that if two lights are seen alternatively with increasing frequency, first the sensation of hue difference is lost and only later the sensation of intensity difference; choosing a frequency when color sensation is already lost but the intensity flicker is still perceived (in the order of 15 Hz), one can equate the “intensity” of the two lights by minimizing the flicker). Based on many investigations, CIE agreed to a table showing the relative visibility of lights of different wavelengths compared to the light with highest visibility in 1924 [2].

Spectral luminous efficiency $V(\lambda)$ for foveal vision at photopic levels: The present standard [3] is based on the table recommended in 1924, practically only interpolating and extrapolating the values with a very minor smoothing made. This $V(\lambda)$ function is the basis of present-day photometry, and due to the fact that the CIE 1931 colorimetry was based on photometry, the $2^\circ \bar{y}(\lambda)$ function was chosen to be equal to the $V(\lambda)$ function. The $V(\lambda)$ function is – more or less – valid (see later) at high luminance levels (accordingly, the $V(\lambda)$ function should be used above 5 cd/m² luminance, and it should mimic the spectral sensitivity of one of the cone signal channels (composed from the L and M cone signals) of human vision for foveal vision (part of the human retina where the spatial sensitivity (visual acuity) is highest.

This part of the retina is covered by a yellowish layer (macula lutea) that functions as a color filter. At larger eccentricity angles, where the macula lutea does not cover the fovea anymore, the eye sensitivity is different, see $V_{10}(\lambda)$ later).

Spectral luminous efficiency $V'(\lambda)$ for foveal vision at scotopic levels: At low light levels, the rods take over the role of vision; this is the range of scotopic vision. The spectral sensitivity of the rods differs from that of the cones. The spectral luminous efficiency for scotopic vision was internationally agreed in 1951 [5] and was standardized in 2004 [4]; it should be used if the luminance is smaller than 0.005 cd/m².

Mesopic spectral luminous efficiency $V_{mes}(\lambda)$: Between scotopic and photopic luminance levels, both rods and cones contribute to the spectral luminous efficiency. CIE published in 2010 a method to calculate the luminance level-dependent spectral luminous efficiency function in this mesopic range [4].

Some Further Visibility Functions

Modified 2° spectral luminous efficiency: It turned out quite early that the values of the 2° spectral luminous efficiency function are lower as would correspond to average human vision, but it took till 1990 that CIE adopted the $V_M(\lambda)$ function [6] and recommended it for applications in visual sciences. For further details on how this function has been derived and what forerunners have been published, see above publication.

Spectral luminous efficiency for large visual fields: There was no internationally accepted spectral luminous efficiency function till 2005, when CIE adopted the $V_{10}(\lambda)$ function based on the 10° standard colorimetric observer's $\bar{y}_{10}(\lambda)$ function [7].

Cone fundamental-based spectral luminous efficiency functions: Recent investigations have shown that in human vision, one of the visual channels provides a luminance-like signal to the brain. Based on detailed investigations,

Spectral Luminous Efficiency, Fig. 1 Some more important spectral luminous efficiency functions

CIE determined the average cone fundamental spectral response functions (spectral responsivities at human eye cornea level) and recommended color matching functions that correspond better to average human color perception as the CIE 2° and 10° standard observer functions [8].

Based on the above, Stockman and coworkers determined an average spectral luminous efficiency function for daylight adaptation [9] taking world population genotype distribution into consideration (the genotype influences the cone fundamental spectral sensitivity $V^*(\lambda)$).

In the following figure, we summarize the different spectral luminous efficiency functions in logarithmic representation. As can be seen, the traditional – and still official – photometric curve is way too low beyond 450 nm, having as a consequence erroneous photometric evaluation of blue LED lights. The $V_M(\lambda)$ curve makes some correction to this discrepancy. The $V^*(\lambda)$ curve is the most recent modification [9] based on cone fundamental signals, average population, and daylight adaptation (earlier $V(\lambda)$ functions have not taken any adaptation into consideration). The $V_{10}(\lambda)$ and $V_{10}^*(\lambda)$ curves differ from each other only very slightly, while the $V'(\lambda)$ function –

as it represents the input from a quite different type of light-sensitive cells – shows markedly different character (Fig. 1).

One has to emphasize, however, that up to now (2013), all practical photometric calculations are based on the CIE 1924 $V(\lambda)$ function and the Meter Convention has endorsed only the $V(\lambda)$ and the $V'(\lambda)$ functions. All other visibility functions have been recommended only for trial and some eye research applications. With the increasing use of LED-based light sources that contain a pronounced spectral maximum in the blue part of the spectrum, prediction errors using the $V(\lambda)$ function become apparent, and the use of more modern spectral luminous efficiency functions might become necessary.

[Spectral power distribution curves](#)

Definition

Spectral power distribution (SPD) is a function of wavelength and describes the amount of optical radiation across part of a spectrum. SPD usually describes optical radiation emitted by a light source, but generally, SPD can be applied to describe optical radiation reflected by an object, or transmitted from a transparent/semi-transparent object.

According to the definition of the Illuminating Engineering Society of North America (IESNA), SPD is “a pictorial representation of the radiant power emitted by a light source at each wavelength or band of wavelengths in the visible region of the electromagnetic spectrum.” Ideally,

SPD should be expressed in units of W/nm. However, in some of the literature, SPD is a general term used to describe any radiometric or photometric quantity as a function of wavelength (with corresponding units). In many conventional cases, SPD is referred to as radiant power per unit area as a function of wavelength, and this should be correctly termed spectral irradiance distribution (or radiance exitance distribution, depending on the context) expressed in units of W/m²/nm. Although based on the definition of the IESNA, SPD is limited to visible light. SPD is generally applicable to ultraviolet radiation, visible light, and infrared radiation. In color applications, SPD in the visible light region (380–780) nm is the main focus of interest, but SPD in the ultraviolet region is also important because it influences the color perception of fluorescent materials.

As the overall power levels of light sources can vary over many orders of magnitude, SPDs are often normalized for easy comparisons of color properties. Such SPDs are referred to as relative SPDs (dimensionless). A relative SPD is usually normalized so that it has a maximum value of 100 (or 1).

Overview

Spectral power distribution is a function of wavelength and describes the amount of optical radiation within a particular range of a spectrum [1–4]. SPD is used to describe not only light sources but also illuminants. The difference between light source and illuminant is that a light source is an actual physical entity, whereas an illuminant may only be a set of values recording its SPD. For example, International Commission on Illumination (CIE) Standard Illuminant A is the SPD of CIE Source A (approximated by an incandescent, tungsten filament light source). Many CIE Standard Illuminants do not exist, that is, there is no actual light source that can realize the SPD defined for such an illuminant. For example, the CIE D series of illuminants represents various phases of daylight, but no source is available for the D illuminants [1, 5]. Figure 1 shows the SPDs

Spectral Power Distribution,

Fig. 1 Spectral power distribution of International Commission of Illumination (CIE) Standard Illuminants A and D65

Spectral Power Distribution, Fig. 2 Spectral power distribution of a 1000 W tungsten lamp

of CIE Standard Illuminant A and Standard Illuminant D65 from 300 to 780 nm, as examples of SPD [6].

In color science, SPD describes the color characteristics of a light source as a function of wavelength over the visible region. SPD is also often used to describe the color characteristics of an

object because optical properties such as transmittance, reflectance, and absorbance in addition to the detector response are typically dependent on the incident wavelength [7]. Knowledge of SPD contains all the basic physical data about the light and serves as the starting point for quantitative analyses of color. However, SPD cannot provide

Spectral Power Distribution,

Fig. 3 Sample spectral power distribution of white light emitting diodes

the human perception of objects [8]. Note that human perception is based on three components: SPD of light, reflectance of objects, and the color-matching function of human observers.

The SPD of light sources can be measured using a monochromator with optical detectors, or a spectroradiometer. An example of experimentally measured spectral irradiance distribution of a 1000 W tungsten lamp representing SPD is shown in Fig. 2. SPDs of other light sources can be found in a lamp manufacturer's manual, for example, or SPD simulators on-line for educational purposes [8].

By engineering SPDs of different light sources, it is possible to obtain the desired color property of light. These technologies have been applied to solid state lighting, such as white light emitting diodes (LEDs). Samples of SPDs of white LEDs are shown in Fig. 3. The “apparent white” of white LEDs is a “mixture” of different colors of light, where blue light is essential, as shown in Fig. 3. There are many ways to obtain precise color quality parameters, such as correlated color temperatures, illuminance, color rendering, luminous efficacy, etc. Note that different SPDs of light can result in similar apparent colors of light, but quite different color quality.

On the other hand, the apparent color of an object can be described by the SPD of the

reflected light from an illuminated surface and is the product of the percentage of reflectance of the surface and the SPD of the light that falls on the surface. Thus, an object may appear differently affected by different light illuminations.

Spectroradiometer

Definition

A spectrometer is an optical instrument designed to measure the spectrum and stimulus of a light source or self-luminous object. The prefix “spectral” is an abbreviation of the phrase “spectral concentration of,” which is defined by the International Commission on Illumination (CIE) as the “quotient of the radiometric quantity taken over an infinitesimal range on either side of a given wavelength, by the range”.

Overview

Basic Principles

A spectrometer receives light, disperses the light, and converts the optical signals (or more generally, electromagnetic radiation signals) to electrical signals. It provides the radiometric quantities in narrow wavelength intervals. Because many sources have line structures, it is useful to sample the spectrum with narrow bandwidth and wavelength increments [1, 2]. In general, spectral irradiance varies from point to point on the surface. In practice, it is important to note how radiant flux varies with direction, the size of the solid angle subtended by the source at each point on the

surface, and the orientation of the surface. Given these considerations, it is often more prudent to use a stricter form of the formula, to account for these dependent relationships [3]. Spectral irradiance is the desired measurement for general spectroradiometry. In practice, the average of the spectral irradiance is measured, shown mathematically as the approximation:

$$E(\lambda) = \frac{\Delta\Phi}{\Delta A \Delta\lambda}$$

where Φ is the radiant flux of the source (SI unit: watt, W) within a wavelength interval $\Delta\lambda$ (SI unit: meter, m), incident on the surface area, A (SI unit: square meter, m²), and the calculated result E is the spectral irradiance. It is more useful to measure wavelength in nanometers; therefore, the submultiples of the SI units of spectral irradiance are often used, for example, $\mu\text{W}/(\text{cm}^2 \cdot \text{nm})$ [3].

A spectrometer is very similar to a spectrophotometer, another optical instrument used to measure an electromagnetic radiation spectrum. However, there are some differences. The name spectrometer is applied to instruments that operate over a very wide range of wavelengths to measure self-luminous objects. An optical spectrometer could include the UV–VIS–IR spectrum; spectrophotometers are usually used in spectral regions near the visible light spectrum. In general, the reflectance or transmittance is measured. For color measurements, spectrometers are used to measure the color of a light source, while spectrophotometers are used to measure the color of an object [2].

Applications

Spectrometers take the spectral radiance of measurements and spectral irradiance is typical. Based on the spectral data measured, the radiometric, photometric, and colorimetric quantities of light can be calculated, providing a complete description of the color of the source [3]. Thus, the spectrometer is an important tool in the color industry as the basis for calibration. Quantities commonly used in the color industry include CIE tristimulus values, CIE chromaticity

coordinates (x, y), correlated color temperature (CCT), color rendering index (CRI), etc. [2].

An automatic scanning spectrometer includes a mechanism to change the wavelength selected by the monochromator and to record the resulting changes in the measured quantity as a function of the wavelength. Many commercial spectrometers have included built-in post-calculation-functions for easy usage of the spectrometer for various applications. The latter is the basic configuration of a spectrometer, which usually includes a dispersing device and a detecting device (i.e. an optical detector or alternative).

This configuration allows the simultaneous analysis of colors. Such an instrument can record a spectral function without mechanical scanning, which may be corrected in terms of resolution or sensitivity, for instance. The absorption spectrophotometer measures the absorption of light by a sample as a function of wavelength.

Sports Lighting

Gilles Page

Signify, Miribel, France

Definition

The purpose of sports lighting is to create the ideal conditions of visibility for those who experience sports facilities.

User Requirements

The great interest of the media in sports events has an important effect on the development of the sports themselves. This, together with the increased leisure time, has resulted in a booming number of active sportsmen and women all over the world, either taking part in the sports as a leisure activity or in amateur and professional competitions.

Consequently, numerous sports complexes have been developed in which all kinds of sports are practiced, from the general physical training sessions to professional activities. In the organization of sports activities and events, the quality of the facilities available is for the utmost importance for pleasure and in the outcome of the competition. Space, a good playing surface, heating/cooling, safety provisions, etc. are all of major importance.

One essential contribution to a successful sports venue, which is still not always recognized as such, is the standard and quality of the lighting system. This, of course, is not only for TV transmissions, where lighting levels of sufficient quality are an absolute necessity to assure an optimal television transmission, but also for the general practicing of the sports, guaranteeing, for example, a clear view of the components, the objects like the ball, and, of course, the indispensable marking of the competitive area itself.

The users of sports grounds can be distinguished according to their activities:

- The players
- The technical staff, referees, and team officials
- The spectators arriving, watching the game, and leaving the sports facility
- Both the television and film crews and the photographers recording the event

The players, referees, and officials must be able to see clearly all that is going on in the competition area so that they can produce their best possible performance and make accurate decisions.

Spectators should be able to follow the performance of the players and the action in an agreeable environment. The latter requirement means that they must be able to see not only the competition area but also its immediate surroundings. The lighting should also enable spectators to safely enter and leave the sports facility. With large groups this safety aspect is very important.

For television and film coverage, the lighting must be able to ensure high-quality color images, not only of the overall action but also close-ups of the players and spectators alike. Closeup images are important to convey the emotions and atmosphere in a stadium to viewers watching at home.

Sports Lighting Classes

As the competence level of athletes increases so does the speed of the action; the visual task becomes more difficult, requiring more light of a higher quality.

In general, five levels of sporting activity are recognized: international and national competition, regional competition, local competition, training, and recreational. These levels are related to the standards of play and the viewing distances of the spectators. These five levels do not all require the same quality of lighting. Lower standards are clearly acceptable for recreation than for national competitions. To cover all five activity levels, three lighting classes are defined:

Class I: Top-level competition such as national and international matches, which generally

Sports Lighting, Table 1 Lighting classes according to CEN [1]

Level of activity	Class I	Class II	Class III
International and national competition	•		
Regional competition	•	•	
Local competition	•	•	•
Training		•	•
Recreational			•

involve large spectator capacities with potentially long viewing distances. Top-level training may also be included in this class.

Class II: Mid-level competition such as regional or local club matches which generally involve medium-size spectator capacities with medium viewing distances. High-level training may also be included in this class.

Class III: Low-level competition such as local or small club matches which do not usually involve spectators. General training and recreation also come into this class (Table 1).

Lighting Criteria

Knowing the general user requirements, it is possible to determine the lighting criteria for each of the different level of activity. The purpose of this section therefore is to identify these lighting criteria and, wherever possible, to derive the lighting parameters of interest in each case.

Illuminance on a Horizontal Plane

The illuminated playing surface forms a major part of the field of view for the players, officials, and spectators. It is the illuminance on this horizontal plane, at ground level, commonly referred to as the horizontal illuminance (E_h), which chiefly serves to establish the adapted state of the eye, by creating a stable visual background against which players and objects will be seen. Because of this an adequate horizontal illuminance on the field is important.

To ensure safety of movement for the spectators when entering and leaving the stands or surrounds, adequate horizontal illuminance in these areas is also required.

Vertical Illuminance

Because it is important to follow the progress of the players and the ball which can be approximated as vertical surfaces, it is the illuminance on the vertical surfaces (E_v) which describes it best. However, experience shows that where the human observer is concerned, there is a good relationship between vertical and horizontal illuminance. Therefore, for all activities with the exception of television broadcasting, if the specified horizontal illuminance is provided and the design rules are followed, the vertical illuminance will be sufficient.

The scene illuminance, and more particularly the vertical illuminance, has a major influence on the quality of the final television or film picture. To guarantee an optimal view and identification of players from all directions, specified illuminances on vertical planes are required. For television or filming with fixed camera positions, it is sufficient to ensure that the illuminances on planes at right angles to the camera positions are adequate. In the case of an unrestricted choice of camera positions, the vertical illuminance on planes facing all four sides of the competition area should be considered.

Uniformity

Good illuminance uniformity is important in order to avoid both adaptation problems for players and spectators. If the uniformity is not adequate, there is a risk that an object or player details, like sponsor logos and emotions, will not be clearly seen at certain positions on the competition area.

Uniformity is expressed as the ratio of the lowest to the highest (E_{min}/E_{max}) illuminance and as the ratio of the lowest to the average ($E_{min}/E_{average}$) illuminance.

Even when the uniformity ratios as defined above are acceptable, changes in illuminance can be disturbing if they occur over a too short distance. This problem is most likely to arise

when panning a television camera. Therefore, the illuminance uniformity for TV/film coverage at a certain grid point has to be expressed as a percentage change from the average adjacent grid points. This is called the gradient.

Glare Restriction

Glare is a subjective factor, for which a practical evaluation system has been described for outdoor sports applications, by CIE (*CIE 112 glare evaluation system for use within outdoor sports and area lighting*), based on extensive field tests [2]. CIE 112 defines a so-called glare rating factor (GR) for which an assessment scale is given from 10 to 90. The lower the value of GR, the better glare situation is. A maximum GR value of 50 is generally specified in high-end sports projects. The validity of the system is restricted to viewing directions below eye level. The development of the glare rating GR assessment method has led to a reliable system that can be used to make a qualitative statement about the suitability of a lighting system before it is installed.

This assessment method is supposed to be used both for predicting degree of glare at the design stage and checking glare situation of installation, but in reality it is almost never used for the latter situation as it is quite impossible (very difficult) to measure reliable glare on site.

It is also a reason why it is important to refer to guidelines for the positioning of floodlights.

Modeling and Shadows

Modeling is the ability of the lighting to reveal form and texture. This “modeling” ability is particularly important to provide a pleasant overall impression of the athletes, objects, and spectators on and around the pitch.

An installation where light only comes from one direction will cause harsh shadows and poor modeling. The players will appear to be pushed into the background and will only be seen from the same direction as which the light comes. From all other directions they will be seen as dark silhouettes only.

Color Properties of Lamps

Color perception is important in most sports, and while some color distortion, attributable to the artificial lighting, is acceptable, there should not be problem being able to distinguish between different colors.

There are two important aspects of the color properties of lamps:

The color appearance of the light. This is the color impression of the total environment created by the lamp.

The color-rendering properties of the lamps used or CIE color-rendering index. This describes how faithfully a range of colors can be reproduced by a light source.

Both the color appearance and the color-rendering properties of lamps are completely dependent upon the spectral energy distribution of the light emitted. An indication of the color appearance of a lamp can be obtained from its correlated color temperature in degrees Kelvin indicated as T_k , which vary mainly between 2000 and 6500 k. The lower the color temperature, the “warmer” the color impression of the light is; the higher the color temperature, the “cooler” or more bluish the impression of the light.

The color-rendering properties of a light source can be indicated by its color-rendering index R_a expressed as numerical values from 0 to 100. A light source having a color-rendering index of 100 will represent all scene colors faithfully and can be compared with daylight.

Because the color rendering is based on the human eye response, a new metrics based on TV camera response, the TLCI, has been developed by the EBU [3]. It is gaining popularity by broadcasters as being a color metric specifically designed for their needs.

Lighting Recommendations

Taking the various lighting criteria discussed in the previous section as a basis, it is possible to draw up two sets of lighting recommendations

for sports venues: one for venues without TV coverage and one for TV coverage, both being derived from the recommendations of the European standard EN 12193 – Sports Lighting [1].

The first set, presented in Table 2, concerns the lighting needs of players, officials, and spectators and covers a wide range of sporting activities and various levels of play, respectively, for outdoor and indoor activities without television coverage.

It should be noted that different practices are used in the USA; the Illuminating Engineering Society (IES) publishes illuminance recommendations for sports and recreation in its lighting handbook [4] that differ from the ones defined in the EN 12193; the main differences are the following:

- Four lighting classes defined.
- Nearly all sports activities have both a horizontal illuminance and a vertical illuminance component.
- Illuminance criteria are based on visual ages of more than half the intended observers.

Therefore, the recommended lighting levels are generally higher than the ones defined in the EN 12193 norm.

The second set is about lighting needs for TV coverage. When considering the lighting for broadcasting, the ideal situation is for the lighting to achieve the best possible standard relative to the events that will be regularly televised and the use of the venue. EN 12193 considers two categories: minimum for acceptable broadcasting and best practice for major events; the lighting criteria corresponding to these two categories are presented in Table 3.

For venues used for professional sports, where TV transmissions happen, the vertical illuminance has a major influence on the quality of a final television picture. EN 12193 requirements call for minimum vertical illuminance at any point of the field of play; this is the minimum lighting level under which the camera can predictably operate and produce quality images of the athlete. Other publications from national or international sports federations exist and may provide slight

	Flicker (%)	< 5	< 1
Glare	GR indoor/outdoor	< 40/< 45	< 35/< 40

differences in the recommendation values and requirements.

Before consulting these tables, the following points should be noted.

Horizontal Illuminance

The horizontal illuminance needed on the playing area for players, officials, and spectators depends on several factors like:

- The size of the playing object
- The reflectance and color of the playing object relative to the reflectance and color of the background surfaces
- The viewing distances
- The speed of the playing object
- Whether the sports facility is located indoors or outdoors

Levels of illuminance for outdoor facilities are usually lower than for the same sports when played indoors; this is due to the corresponding improvement in contrast and adaptation that occurs when viewing a lit object against a dark background such as the night sky.

The illuminances on a horizontal plane needed for competitions with TV coverage are not listed.

Such levels are secondary to the requirements expressed in terms of vertical illuminance.

To ensure the television picture has a well-balanced brightness, the ratio between the average vertical and horizontal illuminance should be as

closely matched as possible but should not exceed the ratio of 0.5–2 times. That is, the horizontal illuminance should not be less than half the vertical illuminance or greater than twice vertical illuminance.

Vertical Illuminance

In practice, the vertical illuminance required for players and spectators will usually automatically be obtained if the requirements regarding the horizontal illuminance are fulfilled.

Where television broadcasting is a requirement, it is necessary to provide an adequate vertical illuminance across the scene viewed by the camera. If the vertical illuminance is not sufficient, good quality broadcast pictures will not be possible.

Television cameras are not able to adapt to changes and fluctuations in lighting level as quickly as the human eye. Therefore, this limitation must be considered when designing lighting systems for televised events.

In most of the sports activities, television cameras will be viewing predominantly vertical objects between the ground and a height of 1.5 m above the ground. In that case, the illuminance should be specified as the illuminance on a vertical plane 1.5 m above the ground facing the direction of the television camera. In other cases, when the main action takes place at a different height, the illuminance should be specified where the main action takes place; for example, for diving the vertical illuminance should be

specified on a vertical plane along the diving fall and into the direction of the camera.

It is now common that many cameras are used, distributed around the arena to obtain closeup action shots from alongside each event area. So, it is important to ensure that the vertical illuminance towards each camera is sufficient.

The recommended illuminances (horizontal and vertical) listed in Tables 2 and 3 are therefore “maintained” values under which the illuminances should never fall during the whole period of operation of the installation.

Illuminance Uniformity

The uniformity requirements for both horizontal and vertical illuminance are more stringent for TV and filming than for the players and spectators, the human eye being less sensitive to nonuniformities than are cameras.

It is principally the horizontal uniformity that determines the brightness range of the overall scene, so this has to satisfy the more stringent requirements.

Color Properties of Lamps

In sports application where color recognition is an important factor especially in case of media coverage, it is essential to use high-color-rendering light sources. For non-televised events, then a lower color-rendering index not less than 60 and up to 80 is generally specified.

For high-end sports events with TV coverage, it is important that true color scenes are properly seen through the TV camera signal. EN 12193 recommends using light sources with a TLCI >80 for major events and at least 60 as a minimum requirement for other cases.

Except in case of TV and film coverage, the color temperature quoted in the recommendations is merely to ensure an acceptable ambiance.

In order to acquire natural color scenes, the camera needs to be white balanced. Because a camera system can only adapt to one color temperature at a time, lighting systems used in combination with daylight should have a color temperature close to that of daylight. In addition, the preferred photographic films for sports usage are daylight balanced to around 5500 K, so light

sources with a color temperature between 5000 and 6000 K are generally recommended in case of TV coverage.

Flicker Effect

A problem for super slow-motion cameras is 50 Hz flicker due to the phasing of the light when using high-intensity discharge lamps. Cameras perceive changes in light levels due to the uneven ratio between the camera scanning frequency and the alternating amplitude of artificial lights powered by mains frequency.

An AC lamp “flashes” at twice the mains frequency. Due to the speed of the flashes, they are imperceptible to the human eye, and the illusion is created that the lighting is continuous. The exposure time of a standard camera corresponds to twice the lighting period. Therefore, a standard camera is integrating each field with an equal amount of light. However, when shooting with a high-speed camera, the behavior of artificial lighting will be shown on the picture, exactly as it is occurring.

In triple-speed mode (150 Hz), the exposure time is one third of the exposure time in single-speed mode. The alternating light amplitude causes different video levels for the three fields. This effect is only visible during slow-motion replay. Since a few years, this problem can be solved by using high-intensity discharge lamps coupled with electronic gear or simply using LED luminaires with appropriate electronic drivers.

Glare Restriction

The visual performance is reduced by glare which shall therefore be limited.

In sports lighting applications, mounting height of the luminaire is a key factor influencing the quality of an installation. This parameter has a big impact on glare and spill light; so, it has to be carefully defined, in relation with the aiming pattern, in order to limit glare while complying with the required lighting level and uniformities.

Additionally, it is wise to avoid installing floodlights in the main viewing directions of the athletes.

Environmental Aspect

The control of stray light from outdoor lighting installations can also be disturbing to people outside the lighted area, for example, to traffic on adjacent roads and to inhabitants of houses in the neighborhood of the sports facility. In some cases, local authorities or municipalities have their own guidelines on such matters, and their advice should always be sought.

It should be noted that stray light falling outside the playing area cannot be effectively controlled by lowering the mounting heights of the floodlights. This only results in luminaires being aimed in a more vertical direction causing even more glare.

In large stadiums it is now a common practice for large video screens or scoreboard systems to be used. In these cases, care must be taken to ensure that luminaires are not positioned too close to these screens as this could cause glare for persons looking up at the screen.

Safety Lighting for Participants

Participant safety is ensured by the safe stopping of an event which might otherwise be dangerous to continue in the absence of lighting.

European Norm EN 12193 about sports lighting specifies safety lighting for some sports activity where the absence of lighting could create a big danger.

The safety lighting shall come on the instant the general lighting fails and last for at least the period specified.

Emergency Lighting

For the purpose of safety and orientation for the spectators, as well as anti-panic lighting in case of mains power failure or emergencies, it is recommended to refer to European Norm EN 1838 (Lighting applications – Emergency lighting) [5].

Continuation of a Sport

For continuation of a sports, the lighting level shall be at least the class III level specified for that sports (see Table 2).

Broadcasting Continuity

The delaying or cancelation of a high-end sports event due to the loss of lighting is unacceptable. Where this is likely to cause a problem, e.g., at professional games and/or where television broadcasting is involved, then provision must be made to give an alternative solution.

Especially for major events broadcasted on TV, it is mandatory that, in the event of power failure, the continuity of the television broadcast shall be guaranteed. The chosen solution has to fit the specification and be relevant for the competition or event to be held in the stadium.

The actual requirement for an alternative power supply and switching method should be specified by sport's governing bodies and their contractual obligations towards the host broadcaster.

The main points to consider are the following:

- Time delay between switching from one power source to another, including the restrike time of lamps
- Lighting level to ensure broadcasting continuity

The highest standard would run the lighting via uninterruptible power supply (UPS) system with an alternative power supply available to supply 100% of the system. This system will provide a complete system with no reduction in lighting quality.

For lower standards (lower continuity lighting level and/or time delay accepted), other alternatives are available depending on several factors like the quality of the local/national power network, investment costs, and maintenance costs.

In that case, solutions can be defined by coupling several supply sources (electricity network, running generators, backup generators).

Spectator Area Lighting

Much of the existing documents about sports lighting mainly specify lighting recommendation on the field of play without taking care of the spectator areas.

For the visual comfort of the spectators, the European norm EN 12193 recommends a minimum value of 10 lx in the spectator area.

In case of TV coverage, it could happen that the broadcaster would specify a lighting level in the spectator area as a ratio of the field of play lighting level in order to suit his production style.

Light Sources

High-intensity discharge lamps have been used for many years as almost the unique light source for sports lighting applications. Since a few years, LEDs are taking over from high-intensity lamps.

A few advantages of the LED versus the high-intensity discharge lamps are:

- The ability to ignite instantaneously whatever the conditions (see section “[Broadcasting Continuity](#)”)
- Easy to create low flicker thanks to electronic drivers, so eliminating the flicker effect in case of slow-motion camera use
- Instant switch on/switch off + individual control of every luminaire, giving the possibility to create light shows before or after the games or during breaks
- Longer lifetime allowing to reduce maintenance cost

Therefore, LED luminaires are more and more adopted for professional venues but also for non-televised event venues for new installations as well as for refurbished ones.

Definition

A standard lamp is used as a reference in photometric, radiometric, and colorimetric measurements for which the calibration is traceable to a primary photometric, radiometric, or colorimetric standard. According to the basic and general

concepts and the associated terms of the International Vocabulary of Metrology, the measurement standard is routinely used to calibrate or verify measuring instruments or measuring systems. In color applications, the standard lamp is the measurement standard that transfers the quantities from the reference measurement standard in a metrological organization [1, 2].

Overview

Colorimeters and spectrometers need to be calibrated against a standard lamp with known standardized data. The International Commission on Illumination (CIE) standard illuminant A is intended to calibrate typical, domestic, tungsten-filament lamps. Its relative spectral power distribution is that of a Planckian radiator at a temperature of approximately 2856 K according to the International Temperature Scale of 1990 (ITS-90) with $c_2 = 14,388 \mu\text{m}$. Also, the definition of CIE source A is used to realize the CIE illuminant A. CIE standard illuminant A can be realized by CIE source A, defined as a gas-filled, tungsten-filament lamp operating at a correlated color temperature of 2856 K. The standard lamp can be a CIE source A to transfer the quantities from the reference measurement standard [3].

To establish the traceability of a measurement system, a working standard lamp with the measurement data is assigned by the substitution procedure to compare the primary standard. A working standard lamp is usually calibrated with reference to a secondary standard lamp that is operated under similar conditions and has a certain certification procedure to verify the performance of quantities with a degree of uncertainty. In general, the working standard lamp is applied for the transfer of photometric and radiometric quantities, such as luminance, irradiance, luminous intensity, luminous flux, CIE chromaticity coordinates, etc. The stable and repeatable transfer standards with a low degree of uncertainty, which have similar characteristics to those of the test lamp, are desired for the measurement system

to transfer photometric and colorimetric units from a national metrology institution (NMI).

Some NMIs are now in charge of developing the light-emitting diode (LED) transfer standard to provide the LED industry with a measurement system that is traceable to SI units, as shown in Fig. 1. Also, the transfer standard carries the photometric and radiometric quantities, which are the alternative standards to the traditional gas-filled lamp.

There are three typical LED standard lamps that have been developed in the NMIs. The traditional LED package is the 5-mm diameter package, which has been used since the early 1960s. The LED die is mounted in the reflector cavity, which bonds two wires from the LED die and connects to the frame. There are many colors of LED packaged in transparent epoxy. Some white ones are mixed the phosphors in transparent epoxy lens. The typical LED package – a 5-mm lamp LED transfer standard – has been developed by the seasoning system and the correction model of temperature and photometric quantities has been applied [4]. Although LEDs have many advantages over conventional sources in becoming a transfer standard, they generate a large amount of heat. The heat not only influences the optical characteristics of LEDs, but also alters the stability and repeatability. Therefore, it is important to design a thermal control system to overcome the temperature problem. The high-powered LED should have a suitable temperature control module to reduce the high temperature on the LED die. Therefore, some NMIs have developed a high-powered LED with a thermal control module for the LED standard lamp that has two light distributions for different applications [5]. We can use the goniophotometer measurement method to provide stable photometry and colorimetry quantities for producing the high-powered LED standard lamp [6].

In addition, some NMIs have developed controllable light distribution and have a lower angular correlated color temperature distribution (ACCTD) LED transfer standard for the various applications of LED measurement systems [7]. Also, NMIs provide the temporal and luminous

Temporal and luminous standard lamp

Standard Lamp, Fig. 1 Various light-emitting diode (LED) transfer standards developed by national metrology institutions

standard lamp for the display measurement instrument [8].

Application (For Example, How to Use the Standard Lamp, Spectral Radiometer)

We can use the spectroradiometer to measure the spectral power distribution of the luminaire. The typical sensor of the spectroradiometer for the visible wavelength is silicon-based. The spectral response is not the same for the measurement range. Moreover, the spectral efficiency of the grating is not the same either. Therefore, we should use the standard lamp to calibrate the spectroradiometer using the replacement method. The standard lamp carries the spectral irradiance standard for the measurement of spectral range calibrated by the metrological institute. We use the spectroradiometer to measure the standard lamp, then correct the

spectral response of the spectroradiometer. Furthermore, using the gas lamp (Xe, Ar, Ne, and Kr), which has distinct spectral lines, the spectral reference calibrates the spectroradiometer for wavelength correction. Therefore, we can use the calibrated spectroradiometer to measure the device under test (DUT).

[Standard illuminating and viewing conditions](#)

Definition

Reflectance and transmittance measurements depend in part on the geometry of illumination and viewing. Accordingly, the CIE has specified illuminating and viewing conditions, namely, 45°:0°a, 45°:0°c, 45°:0°x, 0°:45°, d:0°, 0°:d, de:8°, and di:8°. With the 45°:0° geometry, the

sample is illuminated at an angle of 45° from the normal to the sample surface and viewed perpendicularly to the sample surface or within 10° to the normal. There are three standard configurations of the geometry: 45°:0°a, 45°:0°c, and 45°:0°x. The 45°:0°a has a 10° wide cone of light incident on the sample at 45° to the sample normal. The “a” in 45°:0°a indicated annular meaning that the 10° cone continues uninterrupted all the way around the sample. The 45°:0°c indicates circumferential illumination, which is similar to annular except that it is distributed in discrete locations around the ring. The 45°:0°x geometry uses a single beam at a single azimuth angle. The 0°:45° geometry is the reverse of 45°:0°. The 0°:d (normal/diffuse) geometry is one in which the sample is illuminated by a beam whose axis is at an angle not exceeding 10° from the normal to the sample surface. The reflected flux is collected by an integrating sphere, and viewing is accomplished by a receiver being directed toward an inner wall of the sphere. In all geometries, the viewing cones should not exceed 5°. The d:0° geometry is the reverse of 0°:d. The d:8 hemispherical geometries present the sample with diffuse illumination and approximately normal detection. Diffuse illumination is accomplished by the use of an integrating sphere. Light introduced into the sphere is sent through a series of reflections off the diffuse white sphere wall, quickly resulting in the diffuse illumination incident on the sample. Two standard configurations of diffuse geometry are de:8° and di:8°. The former excludes the specular component and the latter includes it.

Example of Measurement Geometry

Diffuse and directional illumination geometries are used for determining the color performance of the device under test (DUT). This entry introduces the examples of measurement geometries for flat panel displays. In practice, configurations for implementing these illumination geometries are represented as follows [1–6].

Standard Measurement Geometries, Fig. 1 (a)

Type I and (b) type II

Diffuse Illumination

Hemispherical Illumination

Use a light source with an integrating sphere, as a uniform diffuse light source, to illuminate DUT. Place the light-measuring device (LMD) at the measurement port with an inclination angle of θ_D off the normal to the center of the DUT. (See Fig. 1. When θ_D is 8° , the measurement geometry is d:8. The 8:d geometry is the reverse of d:8. The d:8 and 8:d geometries are specified by the CIE as standard viewing/illuminating geometries.) The measurement area covers no less than 500 pixels, and measurement field angle is 2° or less. For the specular reflection excluded measurement, open the cover of the specular port during the test. For the specular reflection

included measurement, close the cover of the specular port during the test.

Directional Illumination

Ring Light Illumination

Use a ring light source to provide uniform directional illumination on the DUT over all azimuth angles at an inclination angle of θ_S (recommend 45°). Place the LMD normal to the center of the DUT (see Fig. 2). The measurement area covers no less than 500 pixels, and the measurement field angle is 2° or less.

Collimated Light Illumination

Use a collimated light source to provide directional illumination on the DUT at an inclination

Standard Measurement Geometries, Fig. 2 Ring light illumination measurement geometry

Standard Measurement Geometries, Fig. 3 Collimated illumination measurement geometry

angle of θ_s . Place the LMD at a viewing angle of θ_D . (See Fig. 3. When θ_s is 0° and θ_D is 45° , the measurement geometry is 0:45. The 45:0 geometry is the reverse of 0:45. The 0:45 and 45:0 geometries are also specified by the as CIE standard viewing/illuminating geometries.) The measurement area covers no less than 500 pixels, and the measurement field angle is 2° or less.

Application 1

Users usually view liquid crystal displays (LCDs) in a bright environment, such as office, living

room, etc. To evaluate the contrast of display devices under ambient light is more practical than that under a dark environment. The results of ambient contrast measurements are affected by different illuminance, view angles, etc. Therefore, the measurement geometry of the ambient illuminance is important for the measurement of ambient contrast for LCDs [7].

For the diffuse illumination, a uniform diffuse-ambient light is provided by a light source with an integrating sphere to illuminate the screen of the display (see Fig. 1). The integrating sphere has plural ports. DUT is placed against the sampling port of the integrating sphere. The light

measurement display LMD is arranged to view the screen through the measurement port. Only one measurement port is in use during the measurement. Measurement ports not in use have covers on them. The inner surfaces of covers are coated with standard white that should have the same reflection properties with the inner surface of the sphere. In addition, the directional illumination can also be provided to illuminate the screen of the display for the measurement of ambient contrast of LCDs.

After setting up the measurement geometry, the procedures of the measurement of ambient contrast of LCDs by using the diffuse illumination are listed as follows.

For the measurement with the specular port closed, warm up the DUT for at least 40 min firstly. Secondly, measure the luminance of full-screen white $(L_W)_{dark}$ and full-screen black $(L_K)_{dark}$ under darkroom conditions. Thirdly, set up the integrating sphere, and turn on its lamp (warm up for at least 30 min). Fourthly, measure the illuminance on the surface of DUT. The illuminance is adjusted to the required levels (200 and 500 lx are typical for a bright living room and an office environment) by controlling the intensity of the light source. It is important to keep the correlated color temperature (CCT) of the light source stable during the illuminance adjustment. Finally, measure the luminance of white (L_W) and black (L_K) of full-screen patterns. The diffuse illumination should be kept stable during measuring processes.

For the measurement with the specular port open, warm up the DUT for at least 40 min firstly. Secondly, measure the luminance of full-screen white $(L_W)_{dark}$ and full-screen black $(L_K)_{dark}$ under darkroom conditions. Thirdly, set up the integrating sphere, turn on its lamp (warm up for at least 30 min), and take out the cover of the specular port. Fourthly, measure the illuminance on the surface of DUT. The illuminance is adjusted to the required levels (200 and 500 lx are typical for a bright living room and an office environment) by controlling the intensity of the light source. It is important to keep the CCT of the light source stable during the illuminance

adjustment. Finally, measure the luminance of full-screen white (L_W) and full-screen black (L_K) . The illuminance should be kept stable during the measurement process.

After the measurement of ambient contrast of LCDs, the ambient contrast can be directly calculated by using Eq. (1), where C_A is the symbol of ambient contrast and L_W and L_K are the luminance of full-screen white and full-screen black, respectively.

$$C_A = \frac{L_W}{L_K} \quad (1)$$

The ambient contrast can also be calculated by using the reflectance. The reflectance of full-screen white ρ_W and full-screen black ρ_K is derived by Eq. (2), and the ambient contrast C_A is calculated by Eq. (3). It is recommended that the reflectance is measured at the illuminance E_{01} not smaller than 1000 lx. In Eq. (3), E_0 is the desired illuminance (200 and 500 lx are typical for a bright living room and an office environment).

$$\begin{cases} \rho_W = [L_W - (L_W)_{dark}] \times \frac{\pi}{E_{01}} \\ \rho_K = [L_K - (L_K)_{dark}] \times \frac{\pi}{E_{01}} \end{cases} \quad (2)$$

$$C_A = \frac{(L_W)_{dark} + \frac{\rho_W}{\pi} E_0}{(L_K)_{dark} + \frac{\rho_K}{\pi} E_0} \quad (3)$$

Application 2

For solid-state lighting luminaries (SSL), the standards are described in the framework of the Energy Star program. One of the standards therein is the IES LM-79 on testing and measuring methods. Hereunder, the measurement of the luminous flux and of the luminous colors using integrating sphere photometers and their related requirements is described. For measurement geometries, the LM-79 recommended by integrating sphere has two kinds: 2π sphere and 4π sphere. In the 2π version, light sources are

operated outside the sphere. The luminous flux emitted from the light source enters the sphere through a measuring aperture. The application range is limited to spotlights of the maximum 2π (hemisphere). In the 4π version, the light sources are operated at the center of the integrating sphere with which all directional radiation can be measured. In the LM-79, it is recommended to measure 2π and 4π sources in the inner part of the sphere. The use of the 2π sphere geometry is only recommended in exceptional cases, i.e., when required due to the dimensions and form of the light source. Therefore, further key concerns of the LM-79 with the integrating sphere are:

- Reflectivity of the sphere coating
- Field of view function of the detectors
- Baffle implementation
- Temperature measurement ability

It is very important to check the key concerns for SSL measurements before using the LM-79 standard.

Stanziola, Ralph A

Michael H. Brill

Datacolor, Lawrenceville, NJ, USA

Ralph A. Stanziola (1931–2007), a consultant and teacher of color technology, was born in Philadelphia, received his B.S. degree in Chemistry from the Philadelphia College of Textiles and Science (now Philadelphia University), and resided most of his life in New Jersey. In his early years, at the Research and Technical Service for the Dyes Department of the American Cyanamid Company, Ralph learned color technology from such pioneers as Orrin W. Pineo and Edward I. Stearns. He next served for 9 years as Technical Representative and General Sales Manager for the Davidson & Hemmendinger Company, and later became a sales manager for the Kollmorgen Corporation Color Systems division, which had acquired Davidson and Hemmendinger.

In 1970, Ralph cofounded Applied Color Systems, Inc. where he eventually became the Executive Vice President and Technical Director. In May 1985, Ralph founded Industrial Color Technology, a consulting company under whose auspices he solved many industrial problems involving color control. For the rest of his life, Ralph remained a consultant for ACS (later Datacolor), instructed their Color Technology

seminars, and helped to create the first video training series on color technology.

Ralph held five US patents [1–5] and authored a large number of technical papers and presentations. He developed the Color Curve System for color communication, and helped the Glad Products Company to develop the now famous “Glad Difference,” *Yellow and Blue Make Green*® seal. Less familiar will be his development (with Bob Swain of Chroma Corp.) of a method of using a colored sample to test the wear of a metal piece. The test consists of extruding a molded plastic piece made of component materials of two different colors, and monitoring the color of the mixture. Earlier, Ralph developed the first colorant-dispenser system driven by computer color matching (1979) and patented a Maxwell-disk-based color simulator (1980). He also codeveloped an asymmetrical color tolerancing system using artificial intelligence algorithms (1991), a photonic visual color simulator using LEDs (late 1990s), and a new version of the Color Rule for testing observers and light booths for metamerism (2006).

Ralph joined the Inter Society Color Council (ISCC) in 1962 and was an active member for the rest of his life. He cochaired several ISCC meetings: the Annual Meeting in Princeton in 1992 that celebrated the 25th anniversary of the AIC; the 1994 joint meeting with the Detroit Color Council (DCC); and the 2003 Williamsburg Conference on Industrial Color Problems held at Philadelphia University. He was instrumental in setting up the Education Interest Group, and was the first to chair the Industrial & Applied Color Interest Group. In recognition of these contributions, Ralph received the 2004 Nickerson Service Award, and in 2005 became an Honorary Member of the ISCC. He also served as *Color Research and Application's* Special Editor for Industrial Applications for 10 years.

In 1995, the Technical Association of the Pulp and Paper Industry presented Ralph with their Finest Faculty Award. As a member of the Federation of Societies for Coatings Technology, he received the Armin J. Bruning Award for his outstanding contribution to the science of color in the field of coatings technology. He was also a member of the American Association of Textile

Chemists and Colorists and the Detroit Colour Council.

Ralph's numerous lectures included computer color matching seminars at the Rensselaer Color Measurement Laboratory (Rensselaer Polytechnic Institute) and at the Munsell Color Science Laboratory (Rochester Institute of Technology). The many personal anecdotes he told in his color courses showed a wealth of experience not available in any book. Some urged him to write a book, but he preferred the humbler route of interacting directly with the world and with other people.

Stereo and Anaglyph Images

Krzysztof Templin

Computer Graphics, Max Planck Institute for Informatics, Saarbrücken, Germany

Synonyms

[Stereo pairs](#); [Stereograms](#)

Definition

Stereo images are pairs of conventional images depicting a scene as seen from two different viewpoints, which correspond to the eye positions of an observer in the scene. When each image of a stereo pair is presented separately to the corresponding eye, the impression of three-dimensionality known as stereopsis arises. Stereo

images find its use in arts, entertainment, and scientific visualization.

An anaglyph image is a method of presentation of a stereo image, in which the images composing the stereo pair are colored with different hues and superimposed. The resulting image is viewed using glasses with matching color filters, so that each eye sees only one of the images and stereopsis can appear. Usually, red and cyan filters are used.

Stereo and Anaglyph Images

Stereo Images

Since human eyes have different vantage points from which they view the world, a point in space may be projected to different positions in the two eyes. The difference between the points of projection is called “binocular disparity” and it is a basis to the impression of depth called “stereopsis” [1]. Stereopsis can be artificially triggered when two images, in which corresponding points have been displaced according to their depth, are presented dichoptically, i.e., one to the left eye and the other to the right eye. The images (called half images) are fused into a percept of a single, three-dimensional image. An important tool for studying stereopsis is a random dot stereogram, where the depth impression is evoked solely by the binocular disparity in isolation from any other sources of depth information [2].

The simplest method of stereo image presentation is free fusion. The half images are shown side by side, and the observer is expected to simply converge or diverge their eyes, until the images overlap. The invention of the first device for watching stereograms is attributed to Wheatstone and dates back to 1838 [1, 3]. The modern presentation methods range from various setups making use of special glasses (color, polarizing or interference filters, time multiplexing) to glasses-free, autostereoscopic displays. Each method has its advantages and limitations, important factors being usability, viewing comfort, and faithful color reproduction. A serious flaw of a stereo system is cross talk, i.e., leakage of the signal intended for one eye to the other eye. Cross talk hinders fusion and in extreme cases can spoil the 3D effect completely.

An important issue in stereoscopy is viewing comfort [4]. Since stereo images are presented in a single plane, they require decoupling the focusing and vergence mechanisms of the observer’s eyes. This restricts the range of depths possible to reproduce to a certain volume around the display, because excessive mismatch between the focusing and vergence points causes significant eye-strain in the observer [5]. Since more distant objects require less refocusing, the comfort zone can be greatly extended by increasing the distance to the display or by using lenses which move back the focusing point. Other sources of discomfort include, but are not limited to, various types of inconsistencies between the half images, e.g., in vertical position, focus, or color balance.

When capturing a stereo image, the distance between the viewpoints does not need to equal the human interocular distance (ca. 64 mm). One situation when this is useful is capturing very distant or very close objects. For the former, there would be hardly any stereopsis if natural separation was used, while for the latter the resulting image could become impossible to fuse. Altering the separation between the viewpoints may be also necessary to maintain plausible proportions of the objects or to fit the content within the comfort zone of the display. Sometimes, the background is captured using different viewpoint separation than the foreground and the outcome is composed into one image [6], or the disparities are adjusted throughout the whole range of depths using image processing techniques [7].

Anaglyph Images

Anaglyph images, first described in 1853 [8], are probably the most widespread presentation method of stereo images. The half images are colored with different colors and superimposed using additive color mixing. Each filter of the glasses lets in the light from the corresponding half image while blocking the light from the other one. Various color combinations are used, such as green-magenta or red-blue; however, the most common one is red-cyan, with the left filter transmitting red light and the right filter transmitting blue and green. Apart from the glasses, this method does not require any special equipment,

Stereo and Anaglyph

Images, Fig. 1 A pair of paper anaglyph glasses with red and cyan filters

Stereo and Anaglyph Images, Fig. 2 A grayscale stereo image presented as an anaglyph image; from left to right: red-cyan, green-magenta, yellow-blue

such as a dedicated printer or display, which makes it very inexpensive and convenient (see Fig. 1). However, since the colors of the image need to be modified, this method suffers from poor color reproduction. Moreover, each half image is manipulated in a different way, so the outcome may cause retinal rivalry. Slight blurriness due to chromatic aberration may be visible in one of the eyes, and some high-end glasses include corrective lenses to counteract this effect. Finally, since the filters often do not separate the two half images perfectly, cross talk may appear.

In the most basic form of anaglyph 3D for RGB displays, one filter transmits one of the primaries and the other filter the remaining two primaries. Hence, three types of anaglyph images are possible: red-cyan, green-magenta, and blue-yellow. The final image is formed by selecting one of the RGB channels from one of the half

images and the remaining two channels from the other (see Fig. 2). The yellow filter transmits most of the perceived colors; however, there is a significant luminance imbalance between the yellow and blue filters. The green-magenta pair is well balanced in terms of luminance but gives rise to noticeable color sheen over a wide range of hues [9]. The colors can be traded off for viewing comfort by converting one or both half images to grayscale or by ignoring one of the channels completely [10].

Several algorithms have been proposed to enhance the quality of the anaglyph image given a pair of filters. If the spectral absorption curves of the glasses and the density functions of the display primaries are known, the creation of an anaglyph image as close as possible to the desired stereo pair can be posed as an optimization problem [11]. By performing a few color matching tasks,

anaglyph image generation process can be adjusted to reduce ghosting [12]. Proprietary systems exist, such as ColorCode 3-D or Inficolor 3D, that combine advanced image processing techniques with careful filter pair selection.

Further improvement in the color reproduction can be achieved by using wavelength multiplexing. Each filter transmits all three primary colors but in slightly different wavelength subbands for each eye. The half images have different gamuts, one leaning toward green and the other toward magenta, but the visual system compensates for the difference, and after a short time it is not visible anymore. Even better color fidelity can be obtained with systems based on light polarization. The disadvantage of both systems in comparison to anaglyph 3D is that in addition to the glasses, they require special displays [6, 10].

Stevens, Stanley Smith

Mark D. Fairchild

College of Science, Rochester Institute of Technology, Rochester, NY, USA

S.S. Stevens was an American experimental psychologist perhaps best known in the world of color science for introducing the psychophysical power law and for collecting data on brightness perception as a function of adaptation [2]. He was even more well known in the general field of experimental psychology and psychophysics for many accomplishments in acoustical psychophysics, his important publications, and founding of the Psycho-Acoustic Laboratory at Harvard University.

Among Stevens' literary contributions to the field are the extensive, and immensely praised, *Handbook of Experimental Psychology* (1951) [3] that provides much information that remains useful more than half a century later and the text *Psychophysics* (1975) [4] that was published posthumously after final editing by his wife. It, too, remains a useful reference on the topic. Among the topics described is the hierarchy of mathematical scales (nominal, ordinal, interval, and ratio) in psychophysics, something else developed by Stevens.

Stevens was an undergraduate student at the University of Utah and then transferred to Stanford where he completed his degree in an undetermined field since the variety of courses he took was so extensive. He then was accepted at the Harvard Medical School, but chose to enroll in Harvard's School of Education to avoid the medical school's \$50 fee and organic chemistry requirement and still have access to Harvard's resources. At Harvard he was transformed by a course on perception taught by E.G. Boring, became Boring's unpaid research assistant, and earned a Ph.D. in Philosophy by the end of his second year there. After some more studies in physiology and physics, he was appointed an instructor in the Psychology Department, where he remained until his death. In 1962, Harvard University agreed to appoint Stevens as Professor of Psychophysics in honor of the field founded by G.T. Fechner.

One of Stevens' most notable papers was entitled "To honor Fechner and repeal his

law," published in *Science* in 1961 [1]. In it, Stevens summarized psychophysical scaling data for a variety of perceptual stimuli (e.g., brightness of light, loudness of sound, hotness of heat, pain of electric shock, etc.) and illustrated that they all could not possibly follow the logarithmic relationship between stimulus and perception predicted by Fechner's Law. Instead, all of his data could be well described by power functions with various exponents, which depend on the perception being scaled. This new relationship is known as the psychophysical Power Law, or the Stevens' Power Law. One technique used to establish the Power Law that Stevens developed is known as cross-modal matching. In these experiments, observers match perceived magnitude of one stimulus (e.g., brightness of light) with another (e.g., loudness of sound).

Stevens' work on brightness is well known in color science and led to the description of a color appearance phenomenon as the Stevens' Effect. This work, published in 1963 by Stevens (no relation) and Stevens, examined the effects of light and dark adaptation on the perception of brightness. Scales of brightness were obtained using magnitude estimations (a Stevens' hallmark) and showed that the contrast of brightness increased with increasing adapting luminance (exponent in the power increases). So, as Stevens showed us, when the level of lighting increases, dark colors look darker and light colors lighter.

Stiles, Walter Stanley

Robert W. G. Hunt

Department of Colour Science, University of
Leeds, Leeds, UK

Dr. W.S. Stiles, OBE, FRS, trained in physics at University College, London, and in mathematics at St. John's College, Cambridge. He spent almost all his working life at the National Physical Laboratory of Great Britain in Teddington.

He was created OBE (Officer of the British Empire) in 1946 for his wartime work on visibility, visual search, and the defensive use of dazzle. He was elected to the (British) Royal Society in 1957 and was awarded the Tillyer Medal of the Optical Society of America in 1965. He served as General Secretary of the Commission Internationale de l'Éclairage from 1928 to 1931, was Chairman of the Colour Group of Great Britain from 1949 to 1951, and was President of the (British) Illuminating Engineering Society from 1960 to 1961.

His earlier work with B. H. Crawford introduced the concept of veiling glare, a subject of

particular importance in street lighting, and other applications of illuminating engineering.

His name is perhaps best known in the Stiles-Crawford effect, the reduction in sensitivity of the retina as the angle of incidence of the light becomes increasingly different from normal.

In the late 1950s, he spent much time and effort in constructing a visual colorimeter for redetermining the color-matching functions of the normal observer. This work, involving measurements on over 50 observers, provided the major basis for what became the CIE 1964 supplementary standard colorimetric observer for field sizes of 10° ; the study also included experiments with a 2° field which confirmed the validity of the CIE 1931 standard colorimetric observer apart from the well-known deficiency in sensitivity at the extreme short-wave end of the spectrum. This work also addressed the phenomenon of rod intrusion: the fact that in fields of 10° size, some input from the rods can be added to that of the cones.

Much of his later work was devoted to the study of increment thresholds: the magnitude of the just-noticeable amount of a stimulus of one wavelength when superimposed on a uniform field of another wavelength. From these studies he identified a series of basic visual mechanisms which he identified as π mechanisms, the significance of which have been a matter for considerable discussion.

Toward the end of his life, he collaborated with Gunter Wyszecki in the production in 1967 of *Color Science: Concepts and Methods, Quantitative Data and Formulas*, published by Wiley, with a second edition in 1982 [1]. This work still provides an enormous amount of useful data and information on color science.

He was dedicated to traditional psychophysical experimental methods and regarded it as very necessary to avoid arguments founded on introspective descriptions of sensations, which he regarded as notoriously difficult to interpret correctly. He therefore had no contact with the area of magnitude estimation pioneered by S.S. Stevens and developed subsequently by other workers in color science.

As a lecturer he was clear and authoritative with a commanding demeanor. Although a man of great intellect and prodigious experience in color science, he was nevertheless always willing to help others in the field who approached him for help. His interests included mathematics, reading, and painting.

Stroop Effect

Colin M. MacLeod
Department of Psychology, University of
Waterloo, Waterloo, ON, Canada

Synonyms

[Color-word interference](#); [Stroop interference](#)

Definition

The Stroop effect is one of the best known phenomena in all of cognitive science and indeed in

psychology more broadly. It is also one of the most long standing, having been reported by John Ridley Stroop in the published version of his dissertation in 1935 [1]. In its basic form, the task is to name the color in which a word is printed, ignoring the word itself. When the word is a color word printed in a mismatched ink color, this is very difficult to do and results in slow, error-prone responding. To illustrate, consider **GREEN**: To say “red” to the ink color is difficult relative to a variety of comparison or control conditions such as naming the color of **XXXXX** or the word **TABLE** or even the word **RED**. The performance cost in the mismatch condition – usually referred to as the incongruent condition – relative to the controls is called the Stroop effect or Stroop interference. Figure 1 provides an illustration of the phenomenon.

Background

Since the very beginning of experimental psychology, it has been clear that words are faster to read than objects or their properties are to name. In his dissertation in 1886, Cattell [2] even went so far as to suggest that word reading is automatic due to extensive practice, introducing the concept of automaticity to cognitive science. Automatic processes can be thought of as unintentional, uncontrolled, unconscious, and fast [3]. Under the automaticity account, people cannot comply with an instruction not to read because reading cannot be “turned off”; hence it is guaranteed that incompatible words will cause interference when attempting to name their print colors.

From early on, the other prevalent explanation of Stroop interference was the relative speed of processing account, which in its simplest form argued that faster processes can affect slower processes but not vice versa [4]. Thus, because words are read faster than colors can be named, interference results when the task is to name the colors and ignore the words. This also fits nicely with Stroop's other finding – that there was no “reverse Stroop” interference when the task was to read the words and ignore the colors: Reading performance for incongruently colored words was

1	2	3	4
red	red	xxx	yellow
yellow	yellow	xxxxxxx	blue
green	green	xxxxxx	red
red	red	xxx	yellow
blue	blue	xxxx	red
green	green	xxxxxx	blue
yellow	yellow	xxxxxxx	green
blue	blue	xxxx	green
green	green	xxxxxx	red
red	red	xxx	blue
blue	blue	xxxx	yellow
yellow	yellow	xxxxxxx	green

Stroop Effect, Fig. 1 An illustration of the Stroop effect. In columns 1 and 2, the task is to read each word in the column aloud, ignoring its print color, and to do so as quickly as possible. This represents Stroop’s (1935) first experiment, where he found little difference in reading time between the experimental condition (column 2) and the control condition (column 1). In columns 3 and 4, the task is to name the print color of each word in the column aloud, ignoring the word itself, again doing so as quickly as possible. This represents Stroop’s (1935) second experiment, where he found dramatic interference in that color naming time in the experimental condition (column 4) was much slower and more error prone than was the case in the control condition (column 3). Note that to make the conditions comparable, the same responses are required for every item in every column

equivalent to that for words printed in standard black ink. Stroop’s results are highly replicable, as MacLeod [5] showed over a half century later.

Since Stroop’s landmark study, many hundreds of studies have sought to understand this superficially simple phenomenon, and many more have used his method to explore key aspects of attention, learning, memory, reading, language, and other cognitive skills [5]. More recently, the Stroop task has also been extended to investigate neural mechanisms [6] and clinical disorders [7], among other issues. Interest in Stroop’s method shows no signs of abating; indeed, it is one of the rare phenomena/tasks where interest seems to be growing rather than diminishing with the passage of time.

The Gradient of Interference

An intriguing feature of the Stroop literature, though, is that there was virtually no follow-up to his work for about 30 years; it is only in the 1960s that research on this phenomenon resumed and then with a vengeance. The simplest explanation of this is that the advent of computer-controlled experiments, and especially the resulting ability to time individual trial stimuli, opened up a rich new realm of investigation for which the Stroop task was ideally suited. But the study that actually relaunched research on color-word interference was reported by Klein in 1964 [8] using multiple-stimulus cards in much the same format as Stroop had used. Klein sought to understand what aspects of the words interfered with naming colors. To do so, he incorporated several new conditions. In addition to the baseline “colors-alone” card, there were six interference cards. As always, the standard incongruent condition – using words incongruent with the print colors – showed large interference. When color words that were not the names of the print colors were substituted, interference was cut in half, implicating a large role for response set in interference. Interference then declined more slowly across color-related words (e.g., *lemon*, *sky*); common, unassociated words (e.g., *put*, *heart*); and rare words (e.g., *sol*, *abjure*) and fell to its smallest – but still reliable – level for unpronounceable nonsense syllables (e.g., *hjh*, *gsxrq*). Clearly, despite the instruction to ignore the word, subjects cannot do so, and the greater the relevance of the word, the greater is the resulting interference with color naming. MacLeod [5] reviews the many studies that have taken up where Klein left off.

Variants of the Classic Stroop Task

In essence, Stroop’s paradigm provides a template for studying interference, and investigators have often mined that template to create Stroop-like tasks suited to their particular research purposes. Figure 2 illustrates some of the many alternate

Stroop Effect, Fig. 2 Illustrations of some interference tasks derived from the Stroop “template.” (a) The picture-word task, where naming the picture while trying to ignore the word results in interference (e.g., compared to a picture containing a row of Xs); (b) the “directional Stroop” task, where stating the direction in which the *arrow* is pointing suffers interference from the incompatible word (e.g., compared to no word or a row of Xs); (c) the “counting Stroop”

task, where counting the number of digits suffers interference from the identity of the digits (e.g., compared to using letters in place of the digits); and (d) the flanker task, where identifying the center letter suffers interference from peripheral (flanker) letters that sometimes also appear as central targets (e.g., compared to flankers that are never central targets)

versions in the literature. The best known is the picture-word interference task [9; A in Fig. 2], in which a conflicting word is embedded in a picture. As with the classic Stroop task, interference is largely unidirectional: Naming the picture shows interference from the word, but reading the word is hardly influenced by the picture. Other common variants include the directional version [10; B in Fig. 2], in which again reading the word is quite unhampered by the mismatched arrow, but there is substantial interference from the embedded word when identifying the direction of the arrow, and the digit version [11; C in Fig. 2], in which counting the number of digits is impaired when the digits themselves are incompatible with their numerosity. Further afield, but clearly related, is the flanker task [12, D in Fig. 2], wherein identification of the central letter is impaired by flankers that sometimes also serve as central targets (relative to flankers that are never targets). The list goes on, and MacLeod [5] reviews some of the more common illustrations, although more have appeared in the ensuing quarter century since that review.

Evidence Against the Speed of Processing Account

Stroop himself interpreted the interference phenomenon that now bears his name as follows: “it seems reasonable to conclude that the difference in speed in reading names of colors and in naming colors may be satisfactorily accounted for by the difference in training in the two activities.” Indeed, the third experiment in his paper actually manipulated training and provided support for this explanation, and more recent studies investigating training have confirmed the importance of experience. Notably, MacLeod and Dunbar [13] trained subjects over multiple days to apply color names to initially unfamiliar white shapes. They then were able to track the growth of interference in naming the print colors of incongruent shapes (e.g., the shape called “red” printed in blue) with extended practice on naming just the shapes in white. As shape naming became more practiced (more automatic), shapes produced more interference with naming colors, and print colors produced less interference with naming shapes.

One striking element to the MacLeod and Dunbar pattern was that there was a point in shape training where shape interference in color naming coexisted equally with color interference in shape naming. Such a result is entirely incompatible with a speed of processing account in that the shapes, although still slower to name than colors, nevertheless interfered with color naming. Two converging results were reported around the same time. First, Glaser and Glaser [14] separated the word and color, allowing one dimension to be presented at varying lags before the other. Most critically, even when the color preceded the word by a time sufficient to allow processing of the color before processing of the word, there was still no “reverse Stroop” interference: The color never interfered with the word. Second, Dunbar and MacLeod [15] transformed the words by rotating them in various ways, such as upside down and backwards. This dramatically slowed word reading time, such that it became slower than color naming time. Yet when transformed words were presented in incongruent colors, they still caused as much interference as did upright words. If relative speed of processing were all that mattered for interference, then interference should have been apparent in the Glaser and Glaser studies when color was sped up but not in the MacLeod and Dunbar studies when words were slowed down: In fact, the converse was true. Although compellingly intuitive and widely accepted [4], then, the speed of processing account does not provide a sufficient explanation of Stroop interference.

Alternative Explanations of Stroop Interference

So how *are* we to explain this apparently powerful and simple effect? In the past 25 years, three major explanations have emerged. The first of these was Cohen, Dunbar, and McClelland’s parallel distributed processing, or connectionist, model, proposed in 1991 [16]. At its core, their theory is a strength theory, designed as it was to capture the training data reported by MacLeod and Dunbar [13]. Processing pathways gain strength with

practice, and relative strength determines likelihood and degree of interference. Thus, given our extensive experience with reading, color-word pathways ordinarily are much more strongly connected to color name responses than are color pathways. When Cohen, Dunbar, and McClelland trained the model in various ways, they were able to reproduce many of the major empirical results in the Stroop literature identified by MacLeod [5].

In 2003, Melara and Algom [17], coming from a fundamental perception perspective, proposed that two factors underlie Stroop interference: dimensional imbalance and dimensional uncertainty. Dimensional imbalance reflects how correlated the two dimensions of a stimulus are and how surprising a stimulus is and determines the ease of recovery of a stimulus representation from memory. Dimensional uncertainty reflects how salient a stimulus is, notably how likely or unlikely it is in the context of other (recently presented) stimuli. Together, these two factors determine the success of attentional selection by focusing on salient, surprising, and/or correlated information contained within each dimension and across the two dimensions of a Stroop stimulus. Each influences excitation of targets and inhibition of distractors. Stroop interference occurs both because there is more uncertainty in the colors than in the words and because the words are more salient than the colors. Their experiments manipulating these two factors were able to produce many of the major empirical results.

Also in 2003, Roelofs [18] proposed his model of Stroop interference, a model situated in an already implemented model of word production (WEAVER++) from the psycholinguistic literature. This also can be viewed as a two-factor model, with processing interactions occurring in the system that carries out language production, modulated by a supervisory attentional system that maintains task control. Roelofs posited that different architectures underlie color naming and word reading, with color naming, because it is conceptually driven, requiring an extra step due to colors not being directly connected to their names, unlike words. His experiments derived from this model also reproduced many of the major results in the Stroop literature.

The Big Picture

Anyone who has tried doing the Stroop experiment themselves knows that the interference caused by an incongruent word in naming its print color is powerful. As soon as we can read, we start to show this interference. Although we think of colors as being processed with ease, the existence of Stroop interference is an indication that there is computation involved in processing color names, a computation that can be disrupted. Some of this interference in the standard Stroop paradigm is response interference (i.e., the word and the color name are different responses within the small set), which reveals little about color processing. But the fact that color words not in the response set and words simply related to colors also produce interference demonstrates the semantic contribution to the Stroop effect.

This remarkable phenomenon has been used in recent years for many purposes, including to help to identify the function of certain brain regions, notably the anterior cingulate cortex and dorsolateral prefrontal cortex, both of which are active when resolving conflict. In the context of the Stroop task, the dorsolateral prefrontal cortex appears to be involved in the relevant executive functions, particularly in maintaining response set (to name the color, not to read the word), whereas the anterior cingulate cortex plays a central role in selecting the appropriate response and evaluating its accuracy [19, 20].

One thing is clear after 80 years: This simple and robust paradigm and the interference phenomenon that it demonstrates continue to provide valuable insights into the operation of cognitive processes. It would have been hard to imagine in 1935 that merely pitting a few colors against their names could provide such an important tool.

Stroop Interference

► Stroop Effect

Structural Color

Richard J. D. Tilley
Queen's Buildings, Cardiff University,
Cardiff, UK

Definition

Structural colors arise when white light incident upon a material interacts with its structure such that some wavelengths (colors) are suppressed and others appear enhanced, without any significant light absorption occurring.

Description and Examples

White light is taken to mean unpolarized light from the sun or its equivalent. All of the visible wavelengths are present in the spectrum, from deep red, wavelength 700 nm, to deep violet, wavelength 400 nm. Structural colors, in the broadest sense, arise when white light interacts with a dielectric (usually transparent) material in such a way that the overall balance of this wavelength spread is disturbed *without* significant energy exchange between the incident beam and the constituents of the material, that is, no specific wavelengths are absorbed by the material during this encounter. The principal processes that give rise to such colors are scattering, refraction/dispersion, reflection, and diffraction. Frequently the structural color observed varies with the viewing angle, a phenomenon termed *iridescence*.

Structural colors were first characterized by Robert Hooke in his description of iridescent peacock feathers (*Micrographia*, 1665). He also gave a technique for distinguishing such structural colors from those that are due to pigmentation – when the color is wetted by an organic solvent, it

will disappear if its origin is structural but will be regenerated unchanged as the solvent evaporates. Examples of structural color abound in nature and include rainbows, halos, the colors of feathers, butterflies, beetles, and plants. The colored holograms used as security labels and for decoration are also structural colors, as are the colors that are seen when white light is reflected from compact discs.

Mechanisms

In the following descriptions, it should be noted that the mechanisms for the generation of structural colors described below are not always easily separated or distinct from each other. Many structural colors involve two or more of these mechanisms to generate the color effect, typified by the rainbow, which arises by a combination of dispersion and reflection.

Scattering

Scattering, which occurs when white light encounters small randomly located particles, gives rise to many colors that are found in nature, including blue skies, blue eyes, and the blue colors of some butterflies and feathers. Blue skies were first explained by Rayleigh, who investigated scattering by a small insulating (non-absorbing) sphere with a diameter less than one-tenth of the wavelength of the incident light. Scattering by such particles is referred to as *Rayleigh scattering*. In the case where a beam of unpolarized light is scattered once only by a single scattering center, the irradiance of the scattered light is proportional to $1/\lambda^4$, where λ is the wavelength of the light incident upon the particle. The blue color of the sky is a direct result of Rayleigh scattering by gas molecules in the atmosphere as the blue-violet region of the incident light is scattered approximately nine times more than red light, the result of which is that the sky away from the sun is perceived to be blue (Fig. 1). Towards sunset, when it is possible to look in the direction of the sun through a thicker layer of atmosphere, the scattering will remove blue light preferentially and the sun and sky will appear red.

Structural Color,**Fig. 1** Blue sky and white clouds, colors caused by light scattering

The irises of all eyes are blue at birth due to scattering. The iris is essentially a transparent material consisting of a composite of various tissues, small crystalline regions, and air vesicles, each of which have differing refractive indices. This inhomogeneity gives rise to preferential scattering of blue light. As the light transmitted through the lens and iris is absorbed in the underlying tissues, only the scattered light reemerges, to give the impression of blue. After some weeks, a pigment may be laid down in the iris and it is this deposited pigment that changes the color of the iris from blue to green or brown.

The “electric” clam, *Ctenoides ales*, has an “electric blue” display that is due to scattering from ambient light. The tissues responsible for this scattering contain a large number of silica spheres, amounting to a volume fraction of approximately 0.35, and of an average diameter of approximately $0.30\ \mu\text{m}$. This size is optimal for the scattering of blue and violet light when in water. The scattering layer is coupled with a strongly absorbing layer, so that the two layers, operating in concert, give rise to intense flashes of electric blue scattered light.

Scattering by larger insulating particles can be described by *Mie scattering* theory. Water droplets or ice crystals of varying sizes, but generally much larger than the wavelength of light, scatter all wavelengths approximately evenly: an effect

seen in clouds, mists, and fogs, which appear white (Fig. 1).

Dispersion

When a beam of white light enters a transparent material, each wavelength travels at a different speed, quantified as the *dispersion* of the material. Dispersion is measured by the refractive index, which is lowest for red light and greatest for violet light.

Because of dispersion, a beam of white light crossing a transparent material spreads out into a spectrum as the different wavelengths follow slightly different paths, with red deviated least and violet the most. This accounts for many colors, including the chromatic aberration of simple glass lenses and the “fire” of diamonds. It is the cause of rainbows, which are produced when sunlight coming from *behind* the observer illuminates a sheet of rain. Light entering each raindrop is dispersed and internally reflected, so as to approximately retrace its path towards the observer. A curtain of randomly oriented raindrops generates a cone-shaped spectrum (Fig. 2). The observer sees the upper part of this cone as an arc, with red outermost and violet innermost.

Halos, colored rings seen around the sun, or rarely the moon, are similar, and, unlike the rainbow, are seen on *looking towards* the sun or moon. These form when light passes through high thin

Structural Color,

Fig. 2 The formation of rainbow colors due to dispersion and reflection

Structural Color,

Fig. 3 Colors in a soap film caused by thin-film reflection

clouds that contain hexagonal ice crystals, which disperse the wavelengths to form visible colors. The most often observed halo subtends an angle of 22° to the observer's eye. As dispersion of the violet light is greater than the red, the circular halo is red internally and blue-violet externally.

Thin-Film Reflection

White light reflected from a transparent material in the form of a single thin film, either in air or on a substrate, can show vivid colors, typified by the colors seen in soap films and thin transparent insect wings (Fig. 3). This color arises because light waves are reflected from the upper surface and the lower surface of the film (Fig. 4). On leaving the film, these emergent waves now have a relative phase shift which is dependent upon the

Structural Color, Fig. 4 The production of thin-film colors, arising from the phase difference between rays reflected from the top (red) and bottom (blue) surfaces of a thin film

thickness of the film, its refractive index, and the wavelength of the light. When white light falls onto such a film, each wavelength will suffer a slightly different phase shift to its neighbors. This leads to interference, so that some wavelengths (i.e., colors) are canceled, while others are reinforced. The film then appears colored to an observer.

Although multiple reflections from both the top and lower surfaces occur, the production of color can be most easily understood if only that part of the incident beam that is reflected off the top surface and that part that is transmitted through the film and reflected once off the bottom surface are considered. At *normal incidence*, it is found that a monochromatic incident beam of wavelength λ reflected back from a thin film of refractive index n and thickness d in air or on a substrate of lower refractive index than the film (or in air) will show constructive interference and so appear *bright* when:

$$2nd = (m + \frac{1}{2})\lambda \quad (m = 0, 1, 2, 3 \dots)$$

When the light is incident at a small angle to the normal, it is possible to use the *approximate* relationship:

$$2nd \cos\theta = (m + \frac{1}{2})\lambda$$

If the film is on a substrate of higher refractive index, the reflected light will show destructive interference and appear *dark* under the same conditions. Similarly, light reflected from a film on a substrate of lower refractive index than the film (or in air) will show destructive interference and so appear *dark* when:

$$2nd = m\lambda \quad (m = 1, 2, 3 \dots)$$

If the film is on a substrate of higher refractive index, the reflected light will show constructive interference and appear *bright* under the same conditions. When the light is incident at a small angle to the normal, it is possible to use the *approximate* relationship:

$$2nd \cos\theta = m\lambda$$

Note that the equations for viewing at an angle do not take polarization into account and must be employed with caution.

To determine the appearance of a film illuminated with white light, the reflectivity has to be summed across all of the wavelengths in the visible. The colors seen depend upon film thickness and cycle through several series or *orders*. The $\cos\theta$ angle dependence given above indicates that as the viewing angle moves away from perpendicular, the color observed moves towards shorter wavelengths: a *blue shift*. Because the color observed depends upon the film thickness and angle of observation, in the case of unstable films such as soap bubbles, the colors swirl and change as the film thins and flexes.

Many decorative films and paints are made by using thin-film iridescence. On bags and gift tags, this is often a thin polymer film, sometimes containing a dye, overlaying a reflective substrate. Metallic car paints often contain flakes of a mineral such as mica overlaid with a thin film of a transparent oxide such as TiO_2 .

A similar effect, but generally with greater brightness, is found if the reflecting object is composed of alternating lamellae of higher and lower refractive index. The multicolored mineral labradorite contains alternating lamellae of feldspars of slightly different constitution and refractive indices (Fig. 5a). The bright metallic-looking colors of many scarab beetles is due to a multilayer structure consisting of chitin and air layers, while in Paua shells, the color arises in layers of nacre, a composite of aragonite (CaCO_3) plates and proteins (Fig. 5b).

The reflectivity of such multilayers depends upon the thickness of the layers, their refractive indices, and the angle of view. Relatively simple formulae have been derived for the reflectivity of stacks where just two layer types are involved, each of which is $\lambda/4$ thick, (called a *quarter wave stack*), viewed at normal incidence. The peak reflectivity of such a stack with refractive indices n_1 and n_2 , of thicknesses d_1 and d_2 occurs at a wavelength given by $2(n_1d_1 + n_2d_2)$.

Structural Color, Fig. 5 (a) Paua shell; (b) Labradorite; both showing color due to multilayer reflection

There are a number of differences between the colors exhibited by multilayers compared to those from single thin films. In particular, the blue-shift observed as the observation angle moves away from normal to the stack is much less pronounced compared to single films.

Diffraction

When light encounters an object with dimensions similar to that of visible wavelengths, the waves are diffracted. The disturbance, called the diffraction pattern, is dependent upon the wavelength of the light and visible colors arise when the incident beam is white light. Two regimes have been explored in most detail, diffraction close to the diffracting object, giving rise to a *Fresnel diffraction* pattern, and far from the object, giving rise to a *Fraunhofer diffraction* pattern.

Isolated Centers

When light encounters a small hole, disc, speck or droplet, with a dimension similar to that of visible wavelengths, the diffracted beams take the form of nested cones with maxima and minima given by:

$$\sin\theta = m\lambda/d$$

where d is the diameter of the object and m takes values of: 0, the straight through beam; 1.220, first minimum (dark ring); 1.635, first bright ring, (called the first-order diffracted beam); 2.333, second minimum (second dark ring); 2.679,

second bright ring (second-order diffracted beam); and so on. For orders other than 0, the angle of scattering is wavelength-dependent so that each diffracted cone will consist of a spectrum, with violet diffracted least and red the most. These ring patterns are seen surrounding the image of a star when observed in a telescope, when they are called Airy's rings. Their appearance is indicative both of the quality of the optics of the system and of the atmosphere.

A dense random distribution of scattering centers of differing sizes will not show color as the orders overlap and cancel. However, if the collection is made up of similar-sized objects, colors can result. This occurs on rare occasions when high clouds are made up of uniformly sized droplets with diameters of the order of 0.003 mm and viewed at an angle of approximately 10–45° from the direction of the sun, a phenomenon called *irisation*. Closely related are the coronae (colored rings) that are sometimes seen by an observer looking towards the source of light, the sun or moon, through mist or thin clouds. They are narrower than halos, usually 1–10° in diameter and surround a white central area called the aureole. The pattern is the Fraunhofer diffraction pattern arising from the randomly distributed droplets in the mist layer. These add together and an observer will see fragments of the diffraction patterns from many droplets or specks, each of which contributes to the overall effect. When the clouds consist of similarly sized droplets or specks, the effect will be strong. Coronae always

show the sequence of colors violet-blue, green, yellow, red, with red outermost.

A multicolored corona-like ring due to diffraction can sometimes be seen to surround a narrow beam white light which has passed through a pane of glass covered with a fine powder or is reflected from a mirror covered with fine dust or droplets.

Sheets

A surface which contains a series of equally spaced parallel grooves or slits with a spacing of about the wavelength of visible light forms a *one-dimensional diffraction grating*. Light incident upon such a grating of spacing d (either in transmission or reflection) will be scattered strongly in directions given by the *grating equation*:

$$d (\sin\theta_i + \sin\theta_m) = m\lambda$$

where θ_i and θ_m are the angles of incidence and diffraction, respectively, of the order m , and θ_m is positive when the diffracted and incident beam lie on the same side of the grating normal and negative when they lie on opposite sides of the normal. The Fraunhofer diffraction pattern will consist of a row of bright spots called *principal maxima*. The spacing of these spots is proportional to $1/d$ and lie along a line perpendicular to the grating grooves. They are separated by much smaller secondary maxima which do not give rise to strong color effects. The zero order, $m = 0$, diffracted beam is equivalent to an undeviated beam (transmission) or specular reflection (reflection). For the other orders, the angle of scattering, θ_m is wavelength dependent so that white light will be spread out into a spectrum, with violet diffracted least and red the most.

Scattering centers, such as pits, protuberances, or apertures distributed across a surface to form a regular lattice with a spacing of the order of the wavelength of light, form a *two-dimensional grating*. Each row on the pattern acts as a one-dimensional grating, and the diffraction pattern may be understood intuitively as arising from intersecting one-dimensional gratings. Each row will give rise to principal maxima, (described by the grating equation) running normal to the row selected, separated by weak intermediary

subsidiary spots that do not give rise to strong colors. A complete pattern will only be seen if the conditions of the grating equation are fulfilled for every row simultaneously. For a rectangular grating illuminated by a beam normal to the grating, the conditions for diffraction are:

$$a \sin\theta_m = m \lambda \text{ (grating spacing } a)$$

$$b \sin\theta_p = p \lambda \text{ (grating spacing } b)$$

Each diffracted order is specified by two indices m and p , so that:

$$d_{mp} \sin\theta_{mp} = mp \lambda$$

where d_{mp} is the spacing of the grating elements along the row giving rise to the diffraction pattern row containing the order mp . As before, the zero-order beam corresponds to undeviated transmission or specular reflection and is not colored. The diffraction orders, each forming a spectrum with violet diffracted least and red the most, will now be arranged on a grid with symmetry that matches that of the grating.

Many iridescent gift tags and bags show two-dimensional diffraction effects. The surface of these consists of a thin plastic film, often overlaying a reflecting layer. The polymer surface is embossed with several sets of grooves. Two sets at right angles give rise to square or rectangular diffraction effects while three sets at 60° give rise to hexagons and star diffraction patterns. Compact discs, which store information by way of ordered tracks of surface pits, similarly act as reflection diffraction gratings and show colors when viewed at the correct angle in white light (Fig. 6).

Three-Dimensional Arrays

Photonic Crystals

The theory of diffraction from crystals, ordered three-dimensional arrays of scattering centers, was first derived with respect to X-ray diffraction. The condition for strong diffraction to occur, Bragg's law, is:

$$m\lambda = 2d \sin\theta_B$$

Structural Color, Fig. 6 Colors generated by a reflection diffraction grating on the surface of a compact disc

Structural Color, Fig. 7 Bragg's law: diffraction by a three-dimensional array of scattering centers

where m is the order of the diffracted beam, (1, 2 ...), d is the distance between the planes of scattering centers giving rise to the diffracted beam, and θ_B is the angle between the incident beam and the scattering planes (Fig. 7).

Three-dimensional ordered crystal-like arrays of scattering centers built from insulating materials with different refractive indices, and dimensions approximately equal to the wavelength of light are a well-known source of intense diffraction color and are now referred to as *photonic crystals*. These materials, also called inverse opals or colloidal photonic crystals, can be made

up of arrays of particles, voids, tubes, rods, and so on, all stacked in a regular crystal-lattice like arrangement.

The behavior of photonic crystals can be illustrated by reference to natural opals. These gemstones consist of arrays of ordered silica spheres embedded in a matrix of amorphous silica. When an opal is illuminated with white light, it strongly diffracts various colors. As the opal is tilted, any particular observed color moves to shorter wavelengths giving a blue shift. To quantify this, Bragg's law must be modified to include the effective refractive index of the opal:

$$m \lambda = 2 d \sqrt{[n_e^2 - \sin^2 \theta_i]}$$

where m is the order of the diffracted beam, d is the spacing between the layers of spheres or voids that make up the diffracting planes of the crystal, and θ_i is the (conventional) angle of incidence of the white light in medium 1 with the *effective refractive index* of n_e . The position of all diffracted beams except for the zero order is a function of wavelength and each diffracted order will be pulled out into a spectrum with violet diffracted least and red the most. As the angle of incidence increases, the wavelength diffracted will decrease, that is, a red reflection at $\theta = 0^\circ$ will move towards green and blue, as described above.

Many beautiful colors in nature are produced by natural photonic crystals created by living organisms. Probably best known are some of the spectacular colors of certain butterflies or beetles, but lesser known creatures, such as the sea mouse, have vividly colored spines due to a photonic crystal. Here just one example is given to illustrate this phenomenon. The green hairstreak, *Callophrys rubi* has the underwings colored a mat green (Fig. 8a). The color arises in the layer of scales that cloak these surfaces. The internal structure of each scale consists of a perforated membrane in the form of a photonic crystal (Fig. 8b), which produces the green color observed.

Cholesteric Liquid Crystals

Cholesteric liquid crystal mesophases are built up of layers that are composed of birefringent

Structural Color, Fig. 8 (a) The green hairstreak butterfly, *Callophrys rubi*; (b) a green scale, showing the internal structure. [(a) Courtesy Dr. J. A. Findlay]

molecules. The simplest are the *chiral nematic phases*. In these phases, the director (the average optical axis of the slightly disordered molecules) rotates as one travels in a direction perpendicular to the sheets of molecules (Fig. 9). The physical reason for the generation of a helical structure is that the molecules in each layer are asymmetric. When such molecules pack together, the interactions are minimized if molecules in one layer rotate slightly compared to those in the layer below so as to reduce intramolecular interactions. Because these interactions are the same from one layer to another, the same twist occurs between each layer. In this way, a uniform helical structure results. The defining scale in these liquid crystals is the distance over which the director rotates by 360° , which is called the *pitch* (p) of the helix. The pitch of the helix can be modified by attaching extra groups to the parent molecule of the structure, a feature widely used in the fabrication of liquid crystal-based devices.

White light incident upon such a layer structure will be colored in the same way as photonic crystals. The color observed is given by Bragg's law, in which the pitch of the spiral is equivalent to d and the observed color changes with viewing angle as in the case of opals. The conditions for this to occur follow Bragg's law, which, for cholesteric liquid crystals, is more often written as:

$$\lambda = 2n_m p \cos \theta$$

where n_m is the average refractive index of the mesophase molecules:

$$n_m = (n_e + n_o)/2$$

and θ is the angle between the incident light direction and the axis of the helix, that is, the normal angle of incidence used in optics.

The helix formed by the molecular stacking can be right- or left-handed, and this influences the polarization of the diffracted beams. Normal white light can be regarded as two beams of oppositely circularly polarized light. When the light is normally incident upon the helix, the beam with the same handedness as the helical arrangement of the mesophase is diffracted (reflected) while the component with the opposite handedness is transmitted. When light falls at an oblique angle to the helical axis, both the transmitted and reflected light will be elliptically polarized.

Structural color showing strong polarization is found in a number of beetles. This color effect was first clarified by Michelson in 1911 for the scarab beetle *Chrysina (Plusiotis) resplendens*. In this insect, the elytra, the hard wing cases that cover the back of the beetle, show a metallic green iridescence. Other related beetles with a similar metallic sheen are *Chrysina (Plusiotis) gloriosa* (green/gold), *Chrysina (Plusiotis) optima* (green/blue), and *Anomala dimidata* (green). The light reflected from these last three insects is left

Structural Color,
Fig. 9 Diffraction from a
 cholesteric chiral nematic
 liquid crystal structure
 (schematic)

circularly polarized, while that from *C. resplendens* shows both left and right circularly polarized components.

A number of plants also exhibit helicoidal structures and reflect metallic/iridescent circularly polarized light. Here the structures consist of helicoidally arranged layers of cellulose fibrils in a noncrystalline matrix. The metallic blue-green fruits of the plants *Margaritaria nobilis* and *Pollia condensate* are colored in this way. The young leaves of the ferns *Danaea nodossa*, *Diplazium crenatosseratum*, *Diplazium tomentosum*, and *Lindsaea lucida*, all show metallic blue iridescence. Similarly, the flowering plant *Phyllagathis*

rotundifolia and the sedge *Mapania caudate* also show metallic colors that arise in helicoidal structures.

The pitch of the helical structure can be modulated by external stimuli, including temperature, a property used in liquid crystal thermometers (Fig. 10). These devices operate in the following way. A series of spots of a cholesteric material are arranged in a row. They are chosen so that the periodicity of the molecular helix in each spot will diffract visible light at a precisely defined temperature. An increment of the temperature, δT , of the order of 1 °C, is engineered between each successive spot by using additives or by slightly

Structural Color,**Fig. 10** A liquid crystal thermometer strip

modifying the cholesteric molecule. Within the design temperature range, each spot will diffract visible light only when the mesophase is at the correct temperature, which causes the appropriate temperature value to shine. On approaching this temperature, each spot will run through a spectrum of colors as the pitch of the helix varies.

Rainbow Holograms

Rainbow or Benton holograms are the brightly colored holograms seen on credit cards, security documents, and so on. The hologram itself consists of a transparent photopolymer film with a reflective backing. To view these holograms, white light passes through the transparent layer and is reflected from the backing layer before returning to the observer. The hologram film imposes information on the incident white light by altering its phase, by different amounts, across the incident beam. This is achieved by a spatial variation in the refractive index of the hologram film. Although this refractive index variation is three-dimensional in nature, it is not ordered, as in a photonic-crystal lattice, but, instead, preserves the complexity of the intersecting wave fronts that formed the hologram. The colors that are seen by the viewer, the reconstructed image, are then produced as a result of interference of the phase modified beams after traversing the film.

The information encoded in the hologram is, in essence, an image of the object seen through a narrow slit-shaped window. Each wavelength present in the white light will create its own window, with red corresponding to most diffracted light and violet the least. Thus an observer on a level with the hologram will see a green-dominated reconstruction, while if the observer moves up, the image color will shift through yellow and orange towards red, or, if the observer moves down, will shift to blue, indigo, and violet. There will still be considerable overlap of colors in parts of the image, dependent upon the viewing distance and angle, so that a multiplicity of colors

and patterns can be picked out as the hologram is tilted and moved.

Definitions

Surface plasmons are collective excitations of conduction electrons at the interface between a

metal and dielectric that are stimulated by electromagnetic radiation.

A *surface plasmon polariton* (SPP) occurs when surface plasmons interact strongly with electromagnetic radiation.

Surface plasmon resonance (SPR) is another synonym for SPP and refers to the coherent (resonant) oscillation of the surface conduction electrons excited by electromagnetic radiation.

A *localized surface plasmon resonance* (LSPR) is a nonpropagating SPP confined to nanostructured surfaces.

The term *plasmonics* is often used to cover the various phenomena sustained by SPP and SPR types of light-matter interactions.

Overview

The electron charge density and its electromagnetic fields propagate as a surface wave along a metal–dielectric interface. The electromagnetic field intensity decays exponentially away from the interface. Material systems with free or almost free electrons will sustain SPP excitation. More generally, an SPP occurs when the real part of the dielectric function of the metal is negative and its magnitude is larger than that of the complex dielectric function. This also means that an SPP can only exist for transverse magnetic polarization since no surface modes exist at the metal surface for transverse electric polarization. For common noble metals, such as gold and aluminum, this condition is met in the visible–NIR wavelength region at the air–metal interface. As an SPP propagates along the metal–dielectric boundary, it is very sensitive to changes that modulate this interface. SPP can be excited by electrons or photons. A planar surface of a good conductor that sustains SPP with given frequency ω and parallel momentum obeys the following dispersion relation [1]:

$$k_{\parallel}^2 = \left(\frac{\omega}{c}\right)^2 \operatorname{Re} \left[\frac{\varepsilon_0 \varepsilon}{\varepsilon_0 + \varepsilon} \right]$$

where $k_{\parallel}$ is the parallel component of the wavevector, $\varepsilon(\omega)$ is the dielectric function of the conductor, c is the speed of light in vacuum, and ε_0

is the dielectric constant of the ambient medium (air or vacuum), also known as the permittivity.

$$\varepsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2}$$

where bulk plasma frequency ω_p is

$$\omega_p = \sqrt{\frac{ne^2}{\epsilon m_{\text{eff}}}}$$

with n and e being the free electron density and electron charge, respectively, and m_{eff} the electron effective mass; ϵ here is the vacuum permittivity. Figure 1 depicts the SPP dispersion relation. At lower wavenumber (mid-IR or lower frequency), SPP exhibits photon characteristics, and the waves extend over many wavelengths into the dielectric space. In this regime, SPP behaves like a grazing-incidence light field. As the wave vector k increases, the dispersion relation tends toward the asymptotic limit of the surface plasma frequency, ω_{sp} . Due to their bound nature, the SPP dispersion relation lies entirely to the right of the light line (photon in air, with $\varepsilon_0 = 1$). In this regime, the out-of-plane component of the SPP wave vector ($k_{\perp}$) is purely imaginary and decays evanescently away from the metal surface. Thus, special phase-matching

techniques such as grating or prism coupling are required to excite SPP.

For an incident electromagnetic wave to excite the SPP, both the frequency and parallel momentum must be conserved. This condition cannot be achieved with air (or vacuum) as the ambient medium at the interface due to wave vector mismatch. For the same reason, an SPP from a smooth flat surface does not radiate into the ambient. It is confined to the metal surface with its amplitude decaying exponentially away from the metal surface. SPP propagates on the metal surface and eventually dissipates its energy as heat through Ohmic loss and electron core interaction. For a relatively absorbing metal such as aluminum, SPP propagation lengths can reach 2 μm when excited with 500 nm (visible, green) radiation. For a low-loss metal such as silver where there is less damping, excitation at the same wavelength increases the SPP propagation length to 20 μm . Moving to a longer wavelength where there is less confinement, for example an excitation wavelength of 1.55 μm typically used for optical fiber-based telecommunication, the SPP propagation length can increase into the mm range. The propagation length of SPP sets the upper size limit for the SPP-based photonic circuitry. However, its strength lies in its ability to transmit information in subdiffraction limited

Surface Plasmons,

circuits as shown in the section on examples and applications below.

Examples and Applications

Gold, silver, copper, and aluminum are among the many metals that exhibit strong plasmonic responses. These metals have long been known to have optical properties distinct from standard dielectrics. In fact, long before scientists began to investigate the optical properties of metal nanostructures, plasmonic nanoparticulates were used to produce brilliant colors in ancient artifacts. One of the best-known examples is the famous Lycurgus cup (Fig. 2) that is on exhibit at the British Museum. This ancient Roman relic was constructed with one of the few dichroic glasses that appear opaque and green in reflected light and a brilliant translucent red in transmitted light. The difference in color is due to the distinct plasmonic properties of colloidal gold and silver which are present in trace amounts in the glass of the cup. Studies from a small fragment of the relic have revealed trace amounts of 20–30 nm colloidal gold and silver nanoparticles which give the glass its unique dichroic properties. Similar inclusions of colloidal metal nanoparticles have been found in brilliantly colored stained glass windows in churches.

Surface plasmon resonance (SPR), also known as SPS, is a popular analytical tool for the study of

biomolecular interaction, the determination of kinetic reaction rates, and the evaluation of binding affinity of measured molecular binding events.

More recently, applications of SPP involve the design and fabrication of metal nanostructures to tune their plasmonic properties. This requires delicate chemical synthesis with protocols designed to disperse metallic nanostructures tagged with desired molecular recognition units or nanofabrication of specifically structured metal nanostructures to enable the confinement and/or propagation of SPP to transmit information. While it may seem impractical to transmit light signals with metal structures, the confinement of SPP to the metallic nanostructures enables the propagation of information in subdiffraction limited circuitry. Because planar plasmonic structures act as waveguides confining SPP along the metal–dielectric boundary, they can be used to route signals on a chip. Metal circuits can be defined lithographically and mass produced as miniature-sized plasmonic devices enabling very high density and fast chips as shown in Fig. 3 below [2].

Another striking application of SPP comes in the form of the localized surface plasmon resonance (LSPR) which is essentially SPP that is confined to small metal nanostructures, most often in the form of metal nanoparticle aggregates. Excitation of an LSPR can be tuned by material composition, size, shape and coupling between nanostructured entities. Similar to SPR, LSPR is widely used in biosensors for the study of small

molecule interactions. Localization of electromagnetic fields at certain regions of the nanostructure due to resonant excitation of SPP is the foundation of many forms of surface enhanced spectroscopy and colorimetry based bioassay.

The detailed mechanism of LSPR is described in the section on surface enhanced Raman

spectroscopy below, as it is the dominant mechanism that enables this form of spectroscopy. Here we will simply describe the photothermal effect and its theranostic application. Gold nanoparticles (NPs) are one of the most studied nanomaterials for applications in the biomedical sciences. Gold NPs are potential drug carriers, photothermal

treatment agents, radiosensitizers, optical imaging contrast agents and have shown great promise for cancer therapy. There are a few different types of gold NPs: solid Au NPs, Au nanoshells, and Au nanorods that are commonly used in biomedicine. These different types of NPs are differentiated by their characteristic localized surface plasmon resonances. Among them, Au nanoshell and Au nanorods are known to exhibit broad LSPR tunability, covering much of the visible and NIR spectral window. Synthetic protocols and surface functionalization methods are well publicized through peer reviewed scientific literatures [3]. The nanoparticles are typically stabilized and guided to the targeted tissues by coating them with polyethylene glycol and antibodies. As mentioned in the earlier discussion, surface plasmon resonance interaction with metal nanostructures is a lossy process with most of its energy being dissipated as heat through Ohmic loss and electron-core interaction. The heat generated through optical excitation of LSPR provides gold NPs with a unique photophysical property to act as an anti-cancer agent. Tumor-specific ligands (e.g., transferrin, folic acid, antibodies) have been attached to the surface of gold nanoparticles for specific targeting of and delivery to tumor sites.

There are currently a few different versions of gold-NP based cancer treatment therapy that are undergoing various phases of FDA (Food and Drug Administration) approval [4]. One version

of such anti-cancer treatment relies on the plasmonic properties of a gold nanoshell. The gold nanoshell can be engineered to resonantly interact with different wavelengths of the light used to excite the LSPR. This is done by tuning the shell thickness of the gold coating over the silica nanosphere. With the LSPR of Au nanoshell tuned to a near-infrared absorption window, it can be delivered to cancer sites with the help of targeting agents as mentioned above. Upon arriving at the tumor site, a near infrared laser is used to excite the Au nanoshell and trigger the photothermal effect. This turns the optical radiation into intense but localized heating sources thereby enabling selective and rapid tumor destruction with minimal damage to surrounding tissues. Photothermal therapy of head and neck cancer is currently under phase I of FDA approval. Phase I of clinical trial is aimed to evaluate safety, determine safe dosage range and identify side-effects of new drugs. Photothermal therapy may also be used in combination with standard chemotherapy and radiation. This concept was pioneered by Professors Naomi Halas and Jennifer West of Rice University in 2004 [5]. Figure 4 below shows therapeutic efficacy and tumor growth over a period of time. The figure showed the original mean tumor size at the beginning of the treatment (day 0) and day 10 of the photothermal therapy. The treatment group (with Au nanoshell injected to tumor site) is shown in green, control group (receives no treatments) in red and sham treatment

Surface Enhanced Spectroscopies

Raman spectroscopy is a vibrational technique which provides a wealth of information on the molecular species under investigation. Its many fields of application include identification and structural characterization of semiconductor materials, authentication of artifacts and legal documents, quality control in pharmaceutical manufacturing and the development of new biophysical tools for disease diagnosis and health monitoring. A major disadvantage of Raman spectroscopy is the inherently small scattering cross-sections of the Raman process, which are typically 12–14 orders of magnitude smaller than fluorescence cross sections. This was why the observation of an unexpectedly large Raman signal from pyridine adsorbed on roughened Ag electrode, reported in 1974 by Fleischmann et al., surprised researchers in the field [6]. The Ag electrode had been roughened through repeated oxidation-reduction cycles in an attempt to develop an in situ monitoring tool that is chemically specific [6]. The authors attributed the large pyridine Raman signal to the increase in number of molecules adsorbed on the increased surface area of the roughened Ag electrode. In 1977, Van Duyne et al. recognized that the large observed intensity could not be accounted for by the increase in the number of scatterers and proposed an electric field enhancement model [7]. Ultimately, it was the 1978 analysis by Moskovits [8] which attributed the predominant contributing factor of SERS (surface Enhanced Raman Scattering) to be the electromagnetic excitation of localized surface plasmon resonance (SPR) sustained by properly designed metal nanostructures. His interpretation cements the electromagnetic enhancement theory for SERS and paved the way for the development of the Plasmonics field. It is important to also note that LSPR is not the sole contributing factor to the inordinate large Raman intensity observed from molecules associated with metal nanostructures.

An alternate theory proposed by Albrecht and Creighton in their 1977 report proposed that resonance Raman scattering from molecular electronic states, broadened by their interaction with metal surface, could be responsible for the increased intensity [9]. It is understood that both factors contribute to the observed SERS signature with the LSPR being the dominating enhancement mechanism.

The plasmonic interpretation of SERS led to the understanding and prediction of many characteristic SERS effects. One of them is the fourth power dependency of the SERS enhancement factor (G) upon the local incident electric field ($|E_0|$); $G = |E_0|^4$. Another well-known characteristic of the plasmonic nature of SERS is the coupling of LSPR between adjacent nanostructures which results in extraordinary local field strength thereby enabling single molecule detection from tightly coupled nanostructures. Figure 5 below shows the false coloured electric field distribution of a single gold nanoparticle and a variety of coupled gold nanostructures.

LSPR is extremely sensitive to composition, morphology, geometry and degrees of aggregation and dielectric properties of the ambient environment as partly demonstrated in Fig. 5 [10]. All these factors, while affecting the overall strength of the observed SERS signal, also enable flexibility in the design of nanostructures to sustain stable SERS.

SERS is a powerful spectroscopic effect that leverages the enormous electromagnetic field enhancement caused by the excitation of an intense, sharp and localized surface plasmon resonance of metal nanostructures. The effect can provide rich structural and chemical information for molecules adsorbed on or bonded to SERS active nanometer-sized metal structures. Recent advances in nanotechnology and nanofabrication techniques have enabled researchers to design SERS active colloidal NP systems with optimized electromagnetic enhancements engendering a large variety of SERS-based bioanalytical and bioimaging applications. The advantages of SERS over standard fluorescent labeling techniques lie not only in its multiplexing capability and superior photostability, but also in the

Surface Plasmons, Fig. 5 Electric field distribution in different 2D geometric gold nanoclusters

potential multimodal functionality provided by the other intrinsic properties of the metal NPs, such as the photothermal response which enables its therapeutic role in the treatment of cancer as outlined earlier [11]. In addition to its cancer fighting ability, the intense and unique signal from SERS nanoparticles also enables diagnostic imaging. SERS labels rival that of fluorescent contrasting agents and can be adapted to most of the fluorescent detection schemes. Figure 6 below shows an example SERS imaging of cell surface receptors in mammalian cells [12]. By the similar targeting mechanism, nanoparticles can be guided towards diseased tissue sites and optical spectroscopy-microscopy can be used as a diagnostic means to pin point the disease sites.

In addition to biomedical applications, SERS is also very popular in security applications and

trace chemical detection owing to its extraordinary sensitivity and information rich spectra.

SPR Sensors

The surface plasmon resonance (SPR) enables many forms of enhanced spectroscopy but the simplest form of SPR sensor relies on very simple SPR reflectivity to detect molecular absorption, binding dynamics such as association and dissociation constants of a multitude of molecules from simple organic molecules, polymers, and DNA to complex proteins and antibodies. In its most common form, a flat thin Au film is deposited or index matched to a prism as shown in Fig. 7 below. Users measure the angle of minimum reflection which corresponds to the maximum absorption of

Surface Plasmons, Fig. 6 (a) Optical image of a HeLa cell labeled with nitrile-reporter and target-specific molecules. (b) SERS intensity map of the nitrile vibrational band with three SERS hot spots I, II and III identified. (c) and (d) SEM (scanning electron microscopy) image of

Surface Plasmons, Fig. 7 Typical SPR sensor setup

the Au film. The reflection angle changes as film thickness changes. This is due to the adsorbed molecules modulating the effective index of

refraction of the film/adsorbate system and hence the plasmon resonance condition. The SPR sensors on the Au film can be pre-functionalized with

a capture molecule. When the molecule of interest is present in the test solution, binding events will occur at the Au-water interface, changing the SPP condition of the Au thin film. This change is then observed as a change in resonance angle. Conversely, when the molecule of interest detaches from the Au surfaces, it also changes SPP resonance condition. SPR sensors are often used to measure association and dissociation constants in addition to the simple binding assay in biological systems. This measurement can also be achieved by varying the incident wavelength to match the effective index of refraction. However, such a setup requires a high accuracy tunable laser source and so poses more technical challenges as compared to the simple angle measurement SPR systems.

The same SPR principle can be applied to localized surface plasmon resonances made available by confining the SPR to a small nanostructure. It is possible to monitor the change in the LSPR resonance condition using a very simple dark-field microscopy setup coupled to a simple desk-top spectrometer and achieve very high density parallel detection of molecular adsorption and desorption events.

Summary

With recent advancements in nanotechnology and materials science, SPP based devices are finding more applications. In addition to its broad applications in biomedical agents, sensors and enhanced spectroscopies, plasmonic devices can now be found in narcotic sensors, solar energy converters, field portable autoclaves and an expanding array of microelectronic devices. While most of these devices are still in early development stages, there is no doubt that the impact of SPP will expand as we gain better

understanding of its physics and a better handle on nanofabrication techniques.

[Four-dimensional color vision](#)

Definition

Tetrachromatic color vision here refers to human color vision that relies on the presence of four types of retinal cone photopigment whose signals are processed independently. By analogy with the classical, psychophysical, definition of human trichromacy [1], a tetrachromatic observer will require four primaries in a color-matching experiment to match any other color. In comparative studies of color vision, the term tetrachromacy usually refers to the presence of four distinct types of photoreceptor [2].

A distinction has been made between strong and weak tetrachromacy [3]. In both cases, there are four types of cone in the retina, but only the former denotes behavioral tetrachromacy, where the cortex gains independent access to a fourth signal allowing the individual to discriminate

colors along a dimension denied to color-normal people.

Conceptual Background

In the case of stimuli presented to the fovea, normal human color vision is trichromatic in that three variables or primary lights are needed to match any given color [1]. Since Thomas Young’s Bakerian Lecture of 1802, it has been thought that the basis of trichromacy is the presence in the retina of three types of “sensitive filament,” now known to be the cone photoreceptors. According to the wavelength of maximal sensitivity, these cones are referred to as S (short-wave sensitive), M (middle-wave sensitive), and L (long-wave sensitive).

To explain the existence of additional types of cone with different spectral sensitivities (M’ or L’), one needs to consider the genetics of the M and L cone photopigments (for review see [4]). Nathans et al. [5] sequenced the M and L protein genes that are located in a tandem arrangement on the X chromosome and found a 98% homology of their DNA. This has been taken as evidence for an evolutionarily recent duplication of an ancestral gene, followed by some degree of divergence of the sequences of the two original copies. Highly similar genes tend to

misalign during meiosis and recombine in different ways. A common outcome of this process is a hybrid gene that consists of part L and part M gene. Importantly, such a hybrid gene will express a photopigment with a spectral sensitivity intermediate to those of the normal L and M cone photopigments [6].

Some 6% of men have such a hybrid gene on their single X chromosome and, as a consequence, will be classified as anomalous trichromats. Specifically, 5% of these men are deuteranomalous (Da), and their color vision relies on inputs from S, L, and L’ cones, while another 1% of men are protanomalous (Pa) having S, M, and M’ cones in their retinæ. Of interest here are the first-degree female relatives (mothers, daughters) of anomalous trichromats. These women are heterozygous for either deutan or protan anomaly and are candidates for tetrachromacy: On one of their X chromosomes, they have the genes for the normal L and M cone photopigments, but on the other they carry a hybrid gene that encodes a spectrally shifted cone photopigment. Figure 1 shows the four normalized spectral sensitivity curves for the S, M, L’, and L cones of a hypothetical carrier of deuteranomaly (cDa).

An early paper by Mollon and colleagues [7] provides a useful analogy to human tetrachromacy. They studied variations of color vision in a basically dichromatic species of New World

Tetrachromatic Vision,
Fig. 1 Normalized spectral sensitivity curves for the S, M, L’, and L cones of a hypothetical carrier of deuteranomaly (cDa)

primate, the squirrel monkey. They discovered in the population pool a range of cone pigments with different spectral sensitivities and, more importantly, behavioral trichromacy in a subset of females. Though no genetic analyses were available at the time, the authors hypothesized – correctly as it turned out – that the origin of these animals' good color discrimination was genetic and afforded to them by heterozygosity at the X-linked locus.

X-Chromosome Inactivation and the Retinal Cone Mosaic

In females, during embryonic development, one of their two X chromosomes is silenced [8]. This process is random with respect to the parental origin of the X chromosome, but once inactivation has taken place in a given cell, it is preserved in all daughter cells. Crucially for tetrachromacy, the different types of expressed photopigment will be segregated in different cone cells so that the retina of a carrier for, say, deuteranomaly will be a mosaic of normal and anomalous cones (S, M, L', and L), and the size of the retinal cone patches will depend on the time of onset of X inactivation and the migration of cones in the developing retina. The analogous case exists for carriers of protanomaly (cPa) though they are much rarer in the population.

What Are the Necessary Conditions for Tetrachromacy?

To allow tetrachromacy, it would seem that two essential conditions should be met: Firstly, in the middle- to long-wave region of the spectrum, the heterozygote must have three photopigments that are sufficiently different in their spectral absorption curves. Secondly, there must be independent neural channels that preserve the ratios of excitations of these photopigments.

- (i) It is known that there is a range of L pigments with different peak sensitivities and similarly a range of M pigments [9]. In particular, a

common polymorphism at site 180 in the L cone photopigment gives an ~ 4 nm spectral difference in sensitivity [4, 5]. Jameson and colleagues have suggested that this polymorphism may indeed underlie tetrachromacy [10]. If true, tetrachromacy would then be predicted to occur in about 47% of the Caucasian population and the question arises as to whether such a relatively small spectral separation between two L photopigments would be sufficient to provide an additional, salient signal [11].

In addition, some hybrid pigments may be present in lower optical density and thus have narrower absorption curves [12]. How big a difference in absorption curve between, say, L and L' is sufficient for tetrachromatic color vision? It may be significant that the strongest candidate for tetrachromacy identified so far (see below [13]) has L and L' cone photopigments with an estimated spectral difference of 12 nm.

- (ii) Color vision does not simply depend on the number and type of retinal cone photopigment. In order to perceive colors and be able to discriminate between them, the inputs from different classes of cone need to be compared and two chromatic, post-receptoral channels were classically identified for this task (for discussion see [14]).

Of particular interest for tetrachromatic color vision is the phylogenetically younger, “red-green” opponent channel. Cells of the parvocellular pathway have receptive fields that are divided into spatially and chromatically antagonistic center and surround regions: In the fovea, midget ganglion cells draw their center input from a single cone of one type (e.g., L or M), whereas the surround input is likely to be drawn indiscriminately from L and M cones (mixed surround) (for review see [15]). Such a channel lends itself to tetrachromatic color vision as its chromatic specificity is determined primarily by the type of cone feeding into the center. Thus, if the signal from a single L' cone is compared to the pooled input of other cones, say $L + L'$, as is the case in Da, a cDa individual too will have the neural basis of making

Tetrachromatic Vision, Fig. 2 Schematic representation of a tetrachromatic cone mosaic with a “deuteranomalous” and a normal red-green channel. For explanation see text

similar comparisons. Figure 2 shows a schematic representation of a tetrachromatic cone mosaic with a deuteranomalous (L' vs $(L + L')$) as well as a normal (L vs $(L + M)$) red-green channel. If both channels are capable of providing salient input to cortical mechanisms, then strong tetrachromacy should result.

Historical Considerations

In the first half of the twentieth century, the majority of scientists concerned with individual differences in human color vision and possible phenotypic manifestations of X-linked heterozygosity believed that female carriers of red-green deficiencies either shared a little in their sons' disability or did not differ in any significant way from color-normal observers (for review see [3]). A different view was held by the Dutch physicist De Vries who, in 1948, explicitly stated that the daughters of a Da father “must be tetrachromatic,” and that it should be possible to demonstrate (strong) tetrachromacy using color mixing experiments. That the existence of an additional cone type in the retina indeed has an effect on color matches was found by Nagy and colleagues

33 years later by demonstrating failure of the additivity law [16]. According to this fundamental law of color matching for trichromats, the addition of a monochromatic light to an existing color match (here a match of a 546 nm and a 660 nm mixture ratio to a 588 nm reference light) should not upset the match even though the overall appearance might be different [1]. Four carriers of an unidentified type, but no color-normal male or female control, changed their matches after chromatic adaptation. Since the carriers were nevertheless capable of making trichromatic matches, they would be classified as weak tetrachromats.

Methodological Issues and Results for Strong Tetrachromacy

Explicit tests for strong tetrachromacy must ensure that a fourth chromatic primary is provided on which the tetrachromat can base her discriminations. Thus, no ordinary RGB color monitor can be used for any test of this kind.

Ideal is a specifically designed colorimeter that allows inclusion and manipulation of the wavelength of n primary lights with independent control of luminance. It would also permit the precise

specifications of spatial and temporal stimulus parameters. Such a system was used by Jordan et al. [13] for the identification of tetrachromats in a Rayleigh-type discrimination test. The stimuli used were in the spectral range from 556 to 670 nm, where S cones are insensitive. A triplet of three successive lights was presented. One light was a red-green mixture (546 + 670 nm) that could vary in the proportion of red, and the other two were a monochromatic yellow (590 nm). Observers were asked to identify the red-green mixture. Since all normal trichromats can make a dichromatic color match in this spectral range, they were expected to fail to detect the mixture light for some red-green mixture and some intensity of the monochromatic yellow. In contrast, a strong tetrachromat was predicted to always detect the mixture: A given light mixture could simulate the excitations that the monochromatic yellow produces in her L and M cones, and a different mixture could simulate the excitations in, say, her L and L' cones; but no mixture of red and green light could concurrently satisfy both these equations. Only one out of 18 cDa (known as cDa29) and none of 7 cPa participants performed according to the prediction. As expected, all control subjects failed to discriminate. Since cDa29 could not make a trichromatic color match with only two primaries available in the Rayleigh region, she was classified as strong tetrachromat.

Another approach to explicitly test for strong tetrachromacy is to ask candidates to discriminate surface colors. The challenge here is that one needs to find stimuli that are metameric (indistinguishable) for normal observers but look distinct to a tetrachromat. Such a test was designed to demonstrate that Da individuals are capable of making discriminations not achievable by normal observers [17] and cDa individuals ought to be able to make the same discriminations if their L vs (L + L') channel is salient enough. Participants were asked to rate how distinct pairs of surface colors (two sets of different blue-yellow acrylic mixtures) looked. Multidimensional scaling (MDS) was then used to reconstruct the subjective color space for each observer. Four out of

nine cDa observers were found to be able to make discriminations on this test, and their MDS solution correlated significantly with the theoretical L vs (L + L') channel. One of these four carriers was cDa29. Molecular genetic analyses of saliva samples taken from these observers confirmed the existence of a hybrid gene for an L' cone [13].

To provide the most conclusive evidence for strong tetrachromacy, a full set of color-matching functions is needed for selected candidates. This would allow direct derivation of the four-dimensional color space of four-cone individuals. Furthermore, the influence of factors such as cone ratios, cone optical density, and absorption by the ocular media must be considered in further tests.

Tetrachromacy in Parafoveal and Peripheral Vision

In extra-foveal human vision, five types of photoreceptor are known to be present – rods, three types of cone, and intrinsically photosensitive ganglion cells, which contain melanopsin. Trichromatic simultaneous matches are possible in extra-foveal vision but are unstable with changes in light level or in adaptive state [1], whereas a tetrachromatic match can be found that is stable [18]. These are the characteristics that would be expected for weak tetrachromacy as defined by Jordan and Mollon [3]. It is true that Bongard and his colleagues [18] found that parafoveal trichromatic matches failed under the special condition where one test field replaced the other, but Brindley [1] describes the failure as a “momentary lightening of the field” at the transition. This could still be considered a case of weak tetrachromacy, since the state of adaptation changes at the moment of transition. Whether, at high light levels, a melanopsin signal contributes to subjective appearance in the periphery [19] is currently an issue of active investigation.

Definition

Following a definition by ASTM, texture can be defined as the visible surface structure depending on the size and organization of small constituent parts of a material, typically surface structure of a woven fabric. Many other materials that are used in the manufacturing industry also show texture, often of very different types. Examples are various types of wood, satin, paper, foods, and injection-molded plastics. This entry focuses on effect coatings, since the characterization of their

texture is advanced as compared to the case for most other materials. Also, effect coatings such as metallic and pearlescent coatings are widely used in the automotive, cosmetics, and packaging industry.

The texture of effect coatings is associated with the spatial variation in appearance caused by non-uniformity of colorant. This texture depends on the type of lighting, as shown in Fig. 1. Under intense unidirectional lighting, glint impression (also known as sparkle) is visible. This is the overall impression of several or many tiny light spots (“glints”) that are strikingly brighter than their surroundings. Under diffuse illumination conditions, the texture of effect coatings changes into diffuse coarseness (also known as graininess). This is the perceived contrast in the light/dark irregular pattern that is visible under diffuse illumination [1].

Overview

Conventional colorimetric results such as the modern color difference equations assume that the so-called reference conditions hold. The

Commission Internationale de l’Éclairage (CIE) recommended the investigation of non-reference conditions. According to one of the reference conditions, samples should be spatially uniform. Since effect coatings clearly do have a texture, their industrial importance explains the large body of research that has been conducted over the past decade on the texture of effect coatings.

Below, the progress is summarized that has been made on different subtopics in this area. Only recently, it became possible to objectively measure the texture of effect coatings. These developments are highlighted, since they also enabled the first quantitative studies on the influence of texture on perceived color differences between effect coatings. Because of these developments, it now has become possible to set tolerances on texture parameters. For color formulation and recipe prediction, models are needed that are able to predict texture values based on concentrations of colorants, similar to, e.g., the Kubelka-Munk theory for color prediction. Finally, it is discussed how the appearance of texture can be accounted for in computer graphics and 3D rendering of objects.

Texture Measurement, Modeling, and Computer Graphics, Fig. 1 (a) Two blue metallic paint samples differing in texture (sparkle, glint impression) as viewed under intense directional light. (b) Two blue metallic paint samples differing in texture (graininess, coarseness) as

viewed under diffuse light. Some other parameters for describing the texture of effect coatings have been introduced as well, and some of them will be discussed further below. However, those parameters generally lack strict definitions

Measurement and Observation of Texture

As long as no clear definitions of texture parameters were introduced and an understanding of the relation between illumination conditions and the type of texture of effect coatings was lacking, no commercial instrument for measuring texture could be developed. After having derived clear definitions and constraints on illumination conditions, a large amount of visual data was collected on different types of texture: diffuse coarseness for diffuse illumination conditions and glint impression for intense directional lighting. This body of data was obtained for hundreds of different effect coatings observed under different angles and illumination conditions. The visual data was correlated with texture parameters that were obtained from image analysis applied on CCD images of the same samples. In this way, algorithms were obtained to train and test prototypes of an instrument [1, 2].

The resulting instrument is the BYK-mac™, which is commercially available from BYK-Gardner since 2007. Similar studies are being conducted by other manufacturers of optical instruments as well [3], whereas also the development of the underlying image analysis algorithms has been taken up by the academic world [2].

Based on feedback from the automotive OEM industry, the set of texture parameters considered to be best applicable for the OEM industry has gradually evolved over the years. A graininess parameter G_r was introduced that has a high correlation with the diffuse coarseness parameter mentioned before. Apart from that, glint impression (sparkle) is considered to have two separate dimensions, called sparkle intensity S_i and sparkle area S_a [4]. An overall parameter sparkle grade (S_G) is no longer thought to be important.

Recently, also lighting booths became available that focus on observing the different types of texture under various geometries, such as the byko-spectra effect light booth.

In 2018, a second commercial instrument to measure texture including sparkle and coarseness,

independent from the BYK-mac™, was launched by X-Rite under the name MA-T12™ (a derived instrument with fewer measurement geometries for reflectance measurements goes by the name MA-T6™).

One major hurdle for further advancement in measuring texture is the absence of a widely accepted set of samples that can act as a scale for sparkle (and similarly also for coarseness/graininess). Such scales were developed as part of the research that led to the BYK-mac instrument [1, 5], but these scales did not become publicly available. In the past few years, a special committee of the CIE has defined a preliminary scale for sparkle and graininess, and the first research publications with these scales show promising correlations between measurement data and visual observations [6]. The CIE intends to conduct further research to determine if these scales need further fine-tuning. Part of this work also aims at developing image analysis techniques to extract numerical values for texture parameters [1, 2, 6], using more generic image processing algorithms for texture analysis.

Influence of Texture on Color Perception

Using artificially generated images of textures, several studies showed that the presence of texture has an influence on perceived color differences. Images exhibiting textured lightness variations have been shown to increase the visual tolerance for lightness deviations. This explains why, for effect coatings, a color difference equation like dE_{CMC} is best used with $l = 1.5$; $c = 1.0$; for solid (untextured) colors, best results are typically obtained for $l = 1.5$; $c = 1.0$.

However, quantitative studies on effect coatings only became possible after 2007 as outlined in the previous section. Based on a large study on 405 effect sample pairs, an expression was derived that quantitatively describes how differences in texture and color combine into a total appearance difference. The validity of this approach was confirmed in later research [5].

Setting Tolerances on Texture

Being able for the first time to measure texture parameters of effect coatings, manufacturing industries decided to include consistency in texture in their criteria for quality control. Among the first industries to investigate how to set industrial pass-fail tolerances on texture are the automotive industry and the plastics industry, where texture matching used to be a long-standing problem for quality control.

Most of the global automotive manufacturers are currently setting texture tolerances, as evidenced, for example, by multiparty meetings of the Detroit Color Council in the USA and BYK-Gardner user meetings in Europe. However, no specific tolerances on texture parameters have been published yet.

Based on perception thresholds of texture parameters, a proposal for realistic tolerances was recently published for different sets of texture parameters: diffuse coarseness, glint impression, graininess, and sparkle grade [7]. Only for the parameters sparkle area and sparkle intensity, the lack of published data makes it not yet possible to derive tolerance values.

Predictive Models for Texture

For color matching, optical models are widely used to optimize color formulations. In the 1940s, Kubelka and Munk developed a model that is still widely used in the paint and textile industry. In order to optimize the concentrations of colorants such that also the texture of an effect coating is matched, a similar model for texture is needed. Studies show that texture parameters like sparkle intensity and graininess can vary greatly with paint composition [8]. However, an accurate optical model for predicting texture based on a physical model like Kubelka-Munk has not been developed yet. The first example of an accurate model for texture uses a very different derivation [9]. It is based on a statistical approach for finding those mathematical terms that contribute

significantly to the texture properties that are to be predicted.

A mathematical-physical model to predict the visibility of sparkle as a function of viewing distance, metallic flake size, and other parameters has been recently developed in analogy to astronomical publications related to the visibility of stars during twilight [10].

Rendering of Texture in Computer Graphics

Digital rendering of three-dimensional objects has become very common in the cinematic and computer game industries. However, for accurate rendering of effect coatings also, the texture aspect needs to be taken into account. Most current approaches either completely ignore texture aspects or utilize a very crude and nonquantitative approach by adding sparkles to the image afterward [11].

Recently, two different approaches were published that do make accurate texture rendering possible. Using a few measured texture values as input as well as reflection measurements from an ordinary multiangle spectrophotometer, it was shown that accurate renderings can be produced [12]. No full BRDF and BTf measurements are needed. The core algorithm was derived from procedures used for determining texture parameter values based on images captured from effect coatings. By reversing these procedures, an algorithm was obtained that produces images resembling effect coatings, based on measured texture parameter values. The algorithm does not aim at simulating the reflection from each and every flake in a scene, but it accounts for their combined effect in an effective way.

In contrast to conventional methods for rendering, the derivation of the algorithms and the verification of the accuracy of the visualizations were both determined using visual tests in which rendered images were directly compared to physical objects. Thus, a truly appearance-based method for rendering color and texture was obtained, with

greatly reduced demands on computation power and disk storage.

In the past few years, a large number of publications have appeared related to the accurate visualization of sparkle, originating from groups working at the Universities of Berkeley and Zürich [13], Alicante, CSIC Madrid, and AkzoNobel [12], the Czech Academy of Sciences and Schlenk [14], and others.

Future Directions

Despite all the work that has been done on texture research over the past decade, this area is still in development. There is a clear need for more accurate image analysis algorithms to extract parameters from CCD images that correlate well with visually perceived texture. For manufacturers of optical instruments, this is an absolute necessity for developing instruments that can form a next generation after the commercial launch of the BYK-macTM in 2007.

Perception studies on the effect of texture on perceived color, or on perceived color differences, is also expected to be an active area of research for the coming decade. Currently, color difference equations are used that are derived from very different types of samples, such as solid colors or textiles. At present, texture can only be accounted for through parametric factors.

Setting tolerances on texture parameters and predicting texture properties based on paint composition are both areas of great industrial importance. Yet, these areas have hardly been explored yet.

For accurate rendering of textured paints, there are a few first publications, but also here the potential for improvement is enormous, and there are many obvious industrial applications in, e.g., the movie and the game maker industry.

Finally, it is good to mention that other types of textures appear in other types of paints. One example are powder coatings, where coarse and fine surface textures are common also in coatings without effect pigments. Recently the first

instrument to digitally measure and control also these textures has been commercially launched [15].

Tincture

Paul Green-Armytage
The School of Media, Creative Arts and Social Enquiry, Curtin University, Perth, WA, Australia

Definition

The word “tincture” has more than one meaning in English. *The Concise Oxford Dictionary* has the following: “**1** a slight flavor or trace. **2** a tinge (of a color). **3** a medicinal solution (of a drug) in alcohol (*tincture of quinine*). **4** *Heraldry* an inclusive term for the metals, colors, and furs used in coats of arms.”

The word is used by specialists in particular fields and is uncommon in general conversation. However, some of the concepts associated with the word, if not the word itself, have potential value for those who are concerned with color and ► [appearance](#). In meaning 2, the word refers to very subtle colors. A reporter might describe a bride’s dress as having a beautiful tincture, white with a tinge of pink.

The word has a particular meaning in heraldry (meaning 4), and this draws attention to the lack of a word in general English usage that could embrace several different aspects of appearance in a single word. In heraldry, tincture includes color, luster, and texture. In coats of arms, the designs can be rendered in colors, “metals” (luster), and “furs” (texture). If tincture could be understood to mean all three aspects of appearance, the tincture of the bride’s dress could mean that the dress fabric also had a smooth texture and a lustrous sheen as well as being white with a tinge of pink.

In heraldry, the names used to identify the tinctures are Norman French. There are five “colors”: *gules* (red), *azure* (blue), *sable* (black), *vert* (green), and *purpure* (purple). Three other colors are found in rare cases and are sometimes referred to as “stains”: *sanguine* (blood red), *tenné* (tawny orange), and *murrey* (mulberry). The “metals” are *or* (gold) and *argent* (silver) – often represented by yellow and white. The “furs” are variations on the theme of ermine and vair (squirrel skins) and are represented by stylized patterns.

Where a figure, such as a cross, is set over a background, the “rule of tincture” is applied: the figure must not be from the same group of tinctures as the background. So a red (color) cross can be placed on a gold (metal) background but not on blue (color). This is to ensure maximum light–dark contrast and, therefore, maximum legibility and ease of identification.

There are lessons in heraldry for graphic designers today. The principles embodied in the rule of tincture are as relevant today as they were in the Middle Ages, and the concept of heraldic tincture is a reminder that there are other aspects

of ► [appearance](#), besides color, that can be exploited in design.

It has been suggested that the word “tincture” might be adopted and promoted with something like its heraldic meaning. “Tincture” could mean the totality of appearance characteristics, not only color, texture, and luster, as in heraldry, but also those other aspects of appearance that have been collected under the term “cesia.” “Cesia” is a term coined by César Jannello. It refers to ► [transparency](#), translucency, opacity, gloss, and specular reflection, each of which can also be represented in scales as from matte via semigloss to full gloss. And if the word “tincture” itself is problematic, with its meanings already established, perhaps another new word could be coined that would embrace all aspects of appearance: color, texture, and cesia.

Definition

Traditional color theory represents a fit-for-purpose amalgam of grounded practical theory, normative design theory, and constructivism. It is underpinned by practical rather than scientific concerns and features a range of constructs, principles, and linked axioms that are largely programmatic. This branch of color theory emerged initially in respect to art practice, and as the professional practices of applied design and design of the built environment developed during the nineteenth and twentieth centuries, traditional color theory became a component of educational curriculum in these fields. However, during the mid- to late twentieth century, traditional color theory was rarely taught as a stand-alone subject but in tandem with practical design projects wherein students explored color application within a context that allowed individual creativity. Traditional color theory features the RYB color model, a conceptual model representing color creation using substance color and primary colors of red, yellow, and blue. A range of color constructs feature in traditional color theory including hierarchical color constructs and color combination constructs, relating to color application in art, applied design, and design of the built environment. Color-related constructs arising from traditional color theory represent a vocabulary frequently used in identifying and applying color in art, applied design, design of the built environment, and across diverse industry sectors. As such, these constructs serve as a *lingua franca*

for architects, artists, design professionals, and those involved with color application and within the broader community.

Introduction

A range of different color theories exist across diverse fields of research and inquiry including art, design, linguistics, phenomenology, physics, psychology, and vision science [1–4]. One of these is traditional color theory, which dates back some centuries and emerged initially in the field of art but gained traction in the fields of applied design and design of the built environment during the late nineteenth and twentieth centuries. As with all branches of theory, traditional color theory is characterized by various ontological and epistemological assumptions, theory-specific constructs, and traditions, plus it is characterized by a key focus on substance color. An evolving branch of color theory, constructs that emerged within traditional color theory in the past have come to represent a vocabulary frequently used among artists, designers, architects, and professionals working in color application across diverse industry sectors.

Defining Traditional Color Theory

The characteristics that distinguish historical traditional color theory and set it aside from other color theories include the following: (a) an ontological focus on substance color exploration and application in art, design, and architecture; (b) consideration of an exemplar set of primary pigment colors from which a large gamut of color nuances can be created; (c) a prescriptive approach to creating and applying color harmony; and (d) the provision of color combination guidelines for color exploration and application which are often used as color strategies in art, design, and architecture [3–6].

From a broad perspective, Green-Armytage identified distinct color categories relevant to color theory, and each of these tends to be underpinned by specific and diverse ontological and epistemological assumptions and traditions

[7]. These categories include conventional color, substance color, formula color, spectral profile color, psychophysical color, inherent color, and perceived color. The ontological focus of traditional color theory is primarily substance color in terms of pigments and dyes and, to a limited extent and by extrapolation, formula color.

The epistemological traditions of traditional color theory represent an amalgam of grounded practical theory, normative design theory, and constructivism [5, 6]. It is underpinned by practical rather than scientific concerns and features a range of constructs, concepts, and axioms that specifically relate to color identification, exploration, and application, as follows:

- a) Color is considered to have three attributes: hue, value, and saturation wherein.
 - a. Hue is the general color family cluster commonly referred to by general color terms such as “red,” “blue,” and “green.”
 - b. Value (also referred to as tone and tonal value) relates to the lightness or darkness (whiteness or blackness) of substance color.
 - c. Saturation (also referred to as chroma and chromaticity), relating to the chromatic intensity of color as represented by a continuum from full chromatic intensity to achromatic.
- b) Hierarchical color constructs include primary colors, secondary colors, and tertiary color.
- c) Color constructs that relate to color relationships and color application include analogous colors, complementary colors, monotone, monochromatic colors, and color chords.
- d) Conceptual color models that feature the RYB color triad and often represented by the two-dimensional RYB color model or three-dimensional versions.
- e) Guidelines for color exploration, color combination, and color application in art, design, architecture, and across diverse industry sectors.

Traditional color theory has continued to evolve over time as evidenced by a shift in focus from a prescriptive approach to color combination for application in art, design, and architecture (e.g., the color theories of Munsell) to an

exploratory approach, as per the color theories of Itten and Albers. This shift represented rebuttal of a deterministic, nomothetic understanding about color (relating to color combination, color application plus responses to color) in favor of a post-positivist, idiographic understanding about color, color combination, and application.

As a result of this shift, prescriptive color combination and color harmony principles and formulae were generally replaced by an approach that acknowledges the complexity of color and which feature a stronger focus on color exploration. For example, both Itten and Albers advocate color exploration, with Albers' suggesting exploratory "practice *before* theory," noting that prescriptive color guidelines and formulae are, "...worn out. No mechanical color system is flexible enough to pre-calculate the manifold changing factors ... in a single prescribed recipe." [8–10] This shift also acknowledged Hård and Sivik's assertion that the number of possible color combinations "is almost infinite," highlighting the futile nature of prescriptive color combination guidelines and formulae for color application [11].

Origins and Development of Traditional Color Theory

Aside from commentary offered by ancient Greek philosophers, Tobias Mayer is credited with conceptualizing and documenting the first RYB color model that subsequently served as a basis for development of traditional color theory [2, 4]. Multiple traditional color theorists since Mayer emerged over time, and these generally featured the RYB triad supported by rationale and discussion. These color theorists include Moses Harris, Philipp Otto Runge, Mary Gartside, George Field, Charles Hayter, J.L.F. MÉRIMÉE, Michel-Eugène Chevreul, Albert Munsell, Johannes Itten, and Josef Albers.

As the nineteenth century segued into the twentieth century, the ontological focus of these color theories remained substance (pigment color), including specific types of pigment color such as gouache paint. In this context, gouache (and earlier variations including body color and

opaque watercolor) had the capacity to create a large gamut of color nuances via RYB triad intermixture and create large, flat areas of opaque color with "hard" edges suitable for professional design output. Research for this entry indicates that numerous works of prominent designers and architects at the time used gouache paint including designs and renderings by Owen Jones, Charles Rennie Macintosh, Henry Van Der Velde, William Morris, Christopher Dresser, and Frank Lloyd Wright plus the majority of lecturers and students at the Bauhaus and subsequent design and architecture schools.

The preliminary course at the Bauhaus, which was undertaken by all students, was initially developed by Johannes Itten. In this course, students explored theories of color, design, and space within the context of practical application exercises. Underpinned by an experiential approach, the curriculum allowed for individual creative expression in tandem with subjective and objective observation. As such, it was acknowledged at the Bauhaus that color did not exist in a vacuum, and hence, traditional color theory was not taught as a stand-alone subject from a purely theoretical perspective. Instead, students were encouraged to explore color relationships and constructs common in traditional color theory within the context of practical color design applications relevant to applied design and architecture [12]. Anecdotal research suggests that the pedagogical approach of the Bauhaus, wherein traditional color theory was taught in context of practical color design application, became the norm, and various iterations of this approach featured in the curriculum of applied design and architecture schools across the Western world including Parsons School of Design (New York) and the Shillito Design School (Sydney). However, aside from the publications of Itten and Albers, plus various textbooks, specific color curriculum details from twentieth century remain largely undocumented to date.

Despite its practical focus, traditional color theory did not feature a structured and documented methodology to identify and communicate color information across different applications or industry sectors. However, a number of

theorists developed practical color atlases based on RYB color including Johann Heinrich Lambert in the eighteenth century, who had the foresight to anticipate the benefits of his *Farbenpyramide* (Color pyramid, 1772) for artists, merchants, and design applications [4]. Similarly, David Ramsay Hay published *A Nomenclature of Colours* (1845) which featured 240 colors based on RYB color [2, 4]. Many of the early color atlases were not widely available and had a limited focus, such as entomology or ornithology. In the mid-twentieth century, Jean-Philippe Lenclos developed a methodology to collect and identify color data relating to the built environment, a methodology that prompted the development of the environmental color-mapping technique. Color matching in art, design, and architecture was conducted manually, and the unreliability of this process proved problematic for those applying color across diverse applications due to color mismatch issues. As a result, color notation systems were developed to aid identification and specification of color in industry including the Munsell color notation and color atlas (initially published 1905, 1913), the RAL color system (launched 1927), the Pantone PMS system (launched 1963), and the NCS color system (launched 1979) [5, 13, 14].

Hierarchical Color Classifications

Traditional color theory and the RYB color model are underpinned by specific hierarchical color classifications. The first level is referred to in the literature as “primary,” “principal,” “simple,” or “basic” colors and represented in the RYB color model as red, yellow, and blue. The next level is referred to as “secondary” or “compound” colors, representing intermixture of these primary colors, and identified in the RYB color model as orange, green, and purple. A third hierarchical level is referred to as “tertiary” color, representing an intermixture of red, yellow, and blue. From the twentieth century onward, these intermixtures do not necessarily represent strictly proportional synthesis of RYB pigment colors; instead hierarchical color classifications represent opportunities to

explore color nuances rather than prescriptive formulae for color creation [2, 3, 5].

In this context, primary, secondary, and tertiary colors represent exemplar hues as opposed to actual hues. In respect to the hierarchical color classification of “tertiary” color, Ruskin muddled the common understanding of the term by suggesting that “tertiary” colors were those that lay *between* secondary colors as this enabled him to avoid what he termed *tiresome* color names [5, 15]. This subordinate understanding of the term “tertiary” color has continued due to Ruskin’s solecism.

RYB Color Model and Illustrations

One of the earliest RYB color illustrations were the hue circles of Moses Harris, published in *The Natural System of Colours* (Fig. 1).

Subsequent traditional color theorists developed similar hue circles and color wheel models including Charles Hayter and George Field. Perhaps the most recognizable color models were those of Albers and Itten, and it is primarily Itten’s color wheel and color star model that often featured as teaching and learning tools in color curriculum that focused on traditional color theory in art, applied design, and architecture schools (Fig. 2).

The RYB color model is a key conceptual model that underpins traditional color theory. It is not intended to illustrate the complexity of color or the multitude of hue nuances achievable via pigment color intermixture but an illustrative model of basic color creation and intermixture.

The RYB color model reflects a similar format of other color models such as RGB and CMY. However, each of these color models is distinctly different in terms of ontology and epistemological traditions and should not be conflated or used substitutionally in any way.

Traditional Color Theory Constructs

A distinguishing factor of nineteenth- and twentieth-century traditional color theories are various constructs intended for color exploration

Traditional Color Theory, Fig. 1 Moses Harris hue circles, 1766 (Illustration facsimile edition, 1963)

Traditional Color Theory, Fig. 2 Itten color wheel model and color star, 1961 (Facsimile illustrations by Zena O'Connor and Geoffrey Gifford, 2021)

and application. These constructs, which tend to differ slightly in definition, often represented guidelines for color exploration in an educational context.

Multiple color constructs, which featured in color curriculum and related textbooks, continue to serve as a lingua franca among artists, designers, architects, and professionals involved

with color application across diverse industry sectors [5, 6].

Aside from the hierarchical color classifications of primary color, secondary color, and tertiary color, additional color constructs that relate to hue include but are not limited to the following:

- Analogues colors – these are colors that share a degree of hue similarity but may differ in tonal value and saturation levels. In early traditional color theories, this construct was referred to as “harmonious” colors, a term that has largely been discarded.
- Complementary colors – also referred to as contrasting colors, these are hues that generally sit on opposite sides of color wheel models within the context of traditional color theory.
- Monochromatic – refers to one hue illustrated in a range of tonal value and saturation levels.
- “Warm” colors and “cool” colors – representing discrete groups of colors that are associated with the appearance of warm or cool contexts, substances, illustrations, or themes.
- Tertiary color wheel which may or may not feature three primary colors at the center surrounded by secondary colors, plus an array of tertiary colors created via intermixture of secondary colors.

Color constructs that relate to tonal value and are often used in color exploration and application include the following:

- Monotone – refers to a range of hues that share similarity of tonal value.
- Shadow palettes – refer to combining groups of colors that share similar tonal values and which have been reduced in hue via the addition of gray.
- Tints and shades – refer to variations of tonal value relative to a set of hues. Tints involve the addition of white, and shades refer to the addition of gray, black, or a contrasting color.
- Key – this term and “chord” have been appropriated from music theory. It refers to the quality of tonal value inherent in a color from *high key* referring to light tonal values, *intermediate key* relating to midtonal values, and *low key* referring to dark tonal values.

- Chords – relate to intervals between the tonal values evident in a group of colors. A broad range of tonal values is referred to as *major chord* and a narrow range as *minor chord*. This terminology is common among those specifying and applying color, including typical examples like *high key*, *major chord* and *low key*, and *minor chord*. In visual communications design and interior design, various chord and key combinations are considered to convey different impressions in terms of ambience and mood.
- Natural tonal value order – the notion that colors that frequently feature on color wheel models exhibit a “natural” tonal value, that is, their tonal values tend to be common in nature and, hence, have a relatively high level of familiarity. When reversing these tonal values from high to low, or vice versa, they are considered to appear unfamiliar, “unnatural,” and therefore discordant.

Additional color constructs that occur in traditional color theories often represented by color effects and included in traditional color theory curriculum as a way of exploring color complexity include the following:

- Discords – generally defined as groups of two or more colors that feature tonal values wherein their tonal value has been reversed according to the “natural tonal value order”.
- Broken color – generally defined as a relatively pure pigment color that has been “broken” or diluted by the addition of white, black, gray, or contrasting color, or alternatively, the overlay of colored texture.
- Dirty color – creating and observing the effect that contextual color may have in reducing the apparent purity of pigment color.

Illustrations that were a relatively frequent occurrence in traditional color theory and which were often the basis for guided color exploration in an educational context include the following:

- Color wheel models and color star models similar to those of Itten.

- Value scales representing achromatic grays at equidistant intervals between white and black. These scales often featured nine-step intervals that included white and black.
- Tonal value wheel which features hues drawn from a color wheel model plus corresponding grays that feature the same tonal value of each individual hue.
- Tonal value charts of a range of different individual hues.
- Tints and shades chart which generally feature a range of hues plus light tonal values and dark tonal values of each hue.
- Analysis of a painting – this exercise devised and implemented by Albers and Itten involved identifying the colors evident in a painting in terms of hue, tonal value, and saturation.

Components of traditional color theory continue to feature in curriculum at art, design, and architecture schools. However, the emergence of digital color technologies has altered the way in which color is created and applied within educational contexts and across diverse industry sectors. Despite this, constructs that emerged in traditional color theory continue to be commonly used and frequently applied by artists, designers, architects, and color design professionals [5, 6].

Definition

Conversion of a colorimetric stimulus from one observer to another.

Transformation of Color Matching Functions, Fig. 1 Comparison of the tristimulus functions of the standard observer defined by the CIE 1931 and CIE 2015 systems of colorimetry

Introduction

Because the X, Y, Z tristimulus functions in the CIE 1931 and 2015 specifications [1, 2] have been derived from different representations of the cone response functions, they do not have a linear relationship (see Fig. 1). In particular, the CIE 1931 functions underestimate the sensitivity for wavelengths below 460 nm. Thus, it is not possible to express an exact relationship between the two sets of tristimulus functions, nor between any corresponding triplets of tristimulus values, by means of a system of equations. Instead, it is necessary to use linear regression to determine an approximation between large numbers of corresponding X, Y, Z values derived from the two sets of basis functions.

Fitting with Real Reflectance Spectra

A dataset of 8714 reflectance spectra was collated from readily available spectral reflectance

measurement sets of real material surfaces over the wavelength range 380–780 nm, with measurement data at intervals of 10 nm or less. Each spectrum was interpolated to 1 nm intervals by the Matlab function `interp1` with the cubic spline option. Where the original wavelength range was smaller, for example, with no data provided below 400 nm or above 700 nm, the reflectance was extrapolated smoothly. X, Y, Z triplets corresponding to all the reflectance spectra were calculated in both the 1931 and 2015 systems at 1 nm wavelength intervals by the standard triple-product method, i.e., multiplying the reflectance spectrum of the sample by the spectral power distribution of the D65 illuminant and by the tristimulus functions of the CIE 2° Standard Observer, and summing over the visible wavelength range. Spectral observer data was obtained from cvrl.org. Errors were calculated as ΔE^*_{ab} from the 1976 CIELAB formulae based on the 1931 X, Y, Z values. The X, Y, Z values were normalized to $Y_w = 100$, with the D65 white point = [95.04, 100.00, 108.86] for the 1931

system and [94.76, 100.00, 107.54] for the 2015 system. All calculations were performed in Matlab over the wavelength range [380–780] nm, using data vectors with 401 elements.

A regression procedure was employed to find the 3×3 matrix $\mathbf{M}$ that would minimize error in the X, Y, Z domain over the full dataset. With the observation vectors as columns, this can be expressed in right-matrix form as follows. (For left-matrix form with row vectors, the transpose should be used.)

$$\begin{bmatrix} X_{1931} & Y_{1931} & Z_{1931} \end{bmatrix} = \begin{bmatrix} X_{2015} & Y_{2015} & Z_{2015} \end{bmatrix} \mathbf{M} \quad (1)$$

A regression fitting over the full set of 8714 real samples yields the matrix $\mathbf{M}_R$ (with values shown here rounded to four decimal places):

$$\mathbf{M}_R = \begin{bmatrix} 0.9815 & -0.0465 & -0.0590 \\ 0.0099 & 1.0629 & 0.0713 \\ 0.0104 & -0.0181 & 1.0028 \end{bmatrix} \quad (2)$$

The inverse matrix is:

$$\mathbf{M}_R^{-1} = \begin{bmatrix} 1.0178 & 0.0455 & 0.0567 \\ -0.0088 & 0.9393 & -0.0673 \\ -0.0108 & 0.0165 & 0.9954 \end{bmatrix} \quad (3)$$

It is convenient to define the transform in Eq. (1) in the direction from 2015 to 1931, so that the fitting errors can be calculated as color differences in CIE $L^*a^*b^*$, based on the 1931 system. The distribution of color errors is shown in Fig. 2, with mean of $0.47 \Delta E^*_{ab}$ and 12.7% of errors above the visibility threshold, assuming the just-noticeable difference (JND) = 1.0. The performance can be improved slightly by fitting with second- and third-order polynomials.

Transformation of Color Matching Functions, Fig. 2 Distribution of color errors in fitting of real samples, expressed in ΔE^*_{ab}

Fitting with Synthetic Reflectance Spectra

To simulate the widest possible range of reflectance spectra that might be encountered in real environments, a large dataset of 800 K synthetic spectra was generated (see separate article). They were constrained to be continuous, single-valued functions of wavelength at 1 nm intervals over the range 380–780 nm, with a maximum slope (first derivative) not exceeding $\pm 0.024 \text{ nm}^{-1}$ and probability density function of the slope similar to that of real spectra. The gradient values can be related to the cross-sectional area (convex hull) of the color gamut. Whereas the real samples fit within cuboidal bounds of approximately $2 < L^* < 98$, $-61 < a^* < 68$ and $-56 < b^* < 103$, the synthetic spectra fill a larger volume of $0 < L^* < 98$, $-118 < a^* < 115$ and $-105 < b^* < 123$. They are more demanding, therefore, as a test of the robustness of any color transformation.

A regression fitting over the full set of synthetic spectra, again with the D65 illuminant, yields the matrix $\mathbf{M}_S$:

$$\mathbf{M}_S = \begin{bmatrix} 0.9804 & -0.0435 & -0.0739 \\ 0.0111 & 1.0593 & 0.0884 \\ 0.0101 & -0.0171 & 0.9982 \end{bmatrix} \quad (4)$$

The inverse matrix is:

$$\mathbf{M}_S^{-1} = \begin{bmatrix} 1.0187 & 0.0430 & 0.0716 \\ -0.0098 & 0.9423 & -0.0842 \\ -0.0104 & 0.0157 & 0.9997 \end{bmatrix} \quad (5)$$

The error distribution has a longer tail than for the real reflectance spectra, with mean of $0.80 \Delta E^*_{ab}$ and 24.3% of errors above the visibility threshold. The change is greater for the Z_{2015} tristimulus value. Testing this matrix on the real samples gives a mean error of $0.52 \Delta E^*_{ab}$ and 16.1% of errors above the visibility threshold (Fig. 3). Hence, fitting to the wider gamut of synthetic reflectance spectra results in a somewhat poorer performance of the matrix on the real reflectance samples.

Transformation Under Illuminant E

The calculations above were all made for Illuminant D65 (standard daylight). Repeating for Illuminant E (equi-energy) with no normalization gives the following transformation matrices:

$$\mathbf{M}_{RE} = \begin{bmatrix} 0.9287 & -0.0451 & -0.0525 \\ 0.0096 & 1.0064 & 0.0664 \\ 0.0077 & -0.0165 & 0.9360 \end{bmatrix}$$

$$\mathbf{M}_{RE}^{-1} = \begin{bmatrix} 1.0758 & 0.0492 & 0.0569 \\ -0.0096 & 0.9921 & -0.0709 \\ -0.0091 & 0.0170 & 1.0666 \end{bmatrix} \quad (6)$$

For regression on the synthetic spectra:

$$\mathbf{M}_{SE} = \begin{bmatrix} 0.9275 & -0.0428 & -0.0649 \\ 0.0110 & 1.0033 & 0.0821 \\ 0.0073 & -0.0154 & 0.9309 \end{bmatrix}$$

$$\mathbf{M}_{SE}^{-1} = \begin{bmatrix} 1.0771 & 0.0470 & 0.0709 \\ -0.0111 & 0.9949 & -0.0885 \\ -0.0086 & 0.0161 & 1.0722 \end{bmatrix} \quad (7)$$

The distribution of color errors for real samples has mean $0.48 \Delta E^*_{ab}$ and 13.5% of errors above the visibility threshold. For synthetic samples, the mean is 0.83 with 25.3% above threshold. Testing the synthetic-fitted matrix with real samples, the mean is 0.54 with 17.1% above threshold.

Conversion of LMS to XYZ

The Stockman-Sharpe 2° cone fundamentals were downloaded from cvrl.org (1 nm linear data). They are defined at 1 nm intervals over the range [390, 780] nm, and each curve is normalized to a maximum value of 1.0 at the peak. In this form, they represent three independent sensors, each of which is univariant with sensitivity dependent on wavelength.

Transformation of Color Matching Functions, Fig. 3 Distribution of color errors in testing of real samples with matrix fitted to synthetic samples

In 2015, the CIE defined tristimulus functions, or color matching functions (CMFs), as a linear combination of the cone fundamentals:

$$\begin{bmatrix} \overline{x}_{2015}(\lambda) & \overline{y}_{2015}(\lambda) & \overline{z}_{2015}(\lambda) \end{bmatrix} = \begin{bmatrix} \overline{l}(\lambda) & \overline{m}(\lambda) & \overline{s}(\lambda) \end{bmatrix} \mathbf{F} \quad (9)$$

where:

$$\begin{aligned} \overline{x}(\lambda) &= 1.94735469\overline{l}(\lambda) - 1.41445123\overline{m}(\lambda) \\ &\quad + 0.36476327\overline{s}(\lambda) \\ \overline{y}(\lambda) &= 0.68990272\overline{l}(\lambda) + 0.34832189\overline{m}(\lambda) \\ \overline{z}(\lambda) &= 1.93485343\overline{s}(\lambda) \end{aligned} \quad (8)$$

where $\overline{l}(\lambda)$, $\overline{m}(\lambda)$, $\overline{s}(\lambda)$ are the Stockman & Sharpe [5] 2-deg cone fundamentals, adopted by the CIE in 2006. The coefficients were chosen to make the values of the CMFs always positive (i.e., no negative lobes) and to equalize the integrals (i.e., areas under the curves) of all three functions for an equal energy white.

With the observation vectors as columns, Eq. (8) can be expressed in right matrix form as:

$$\mathbf{F} = \begin{bmatrix} 1.94735469 & 0.68990272 & 0 \\ -1.41445123 & 0.34832189 & 0 \\ 0.36476327 & 0 & 1.93485343 \end{bmatrix} \quad (10)$$

Computation was performed as above, calculating cone responses and tristimulus values at 1 nm intervals over the range [380, 780] nm, using the equi-energy white (Illuminant E) and the set of real reflectance spectra. L, M, S values were set to zero in the interval [380, 389] nm. Responses were not normalized. For the 1931 system, the white point is $X_w = Y_w = Z_w = 106.86$, and for the 2015 system $X_w = Y_w = Z_w = 113.04$. For LMS, the integrated responses to equi-energy

Transformation of Color Matching Functions, Fig. 4 Long, medium, and short (LMS) cone fundamentals defined by Stockman and Sharpe

white are not equal: $[L_w, M_w, S_w] = [115.98, 94.82, 58.42]$.

Regression was applied to find the best-fitting matrix between the corresponding sets of triplet values $[L, M, S]$ and $[X, Y, Z]_{2015}$. The transformation matrix resulting from the regression is:

$$\mathbf{F}_{\text{RE}} = \begin{bmatrix} 1.9474 & 0.6899 & 0 \\ -1.4145 & 0.3483 & 0 \\ 0.3648 & 0 & 1.9349 \end{bmatrix}$$

$$\mathbf{F}_{\text{RE}}^{-1} = \begin{bmatrix} 0.2106 & -0.4171 & 0 \\ 0.8551 & 1.1773 & 0 \\ -0.0397 & 0.0786 & 0.5168 \end{bmatrix} \quad (11)$$

$\mathbf{F}_{\text{RE}}$ is identical to $\mathbf{F}$, apart from the number of decimal places, proving that the regression method works correctly. The same result is obtained for regression over the synthetic spectra and with other illumination sources.

We now wish to convert L, M, S to the conventional CIE 1931 tristimulus values X, Y, Z . The relationship can be expressed as:

$$\begin{bmatrix} X_{1931} & Y_{1931} & Z_{1931} \end{bmatrix} = \begin{bmatrix} L & M & S \end{bmatrix} \mathbf{G} \quad (12)$$

Regression fitting over the set of real samples for equi-energy illumination yields the matrix:

$$\mathbf{G}_{\text{RE}} = \begin{bmatrix} 1.8151 & 0.6064 & -0.0565 \\ -1.3102 & 0.4144 & 0.0974 \\ 0.3537 & -0.0483 & 1.7919 \end{bmatrix}$$

$$\mathbf{G}_{\text{RE}}^{-1} = \begin{bmatrix} 0.2663 & -0.3863 & 0.0294 \\ 0.8491 & 1.1664 & -0.0367 \\ -0.0297 & 0.1077 & 0.5513 \end{bmatrix} \quad (13)$$

Regression fitting over the set of synthetic samples for equi-energy illumination yields:

$$\begin{aligned} \mathbf{G}_{SE} &= \begin{bmatrix} 1.8138 & 0.6088 & -0.0697 \\ -1.3081 & 0.4100 & 0.1203 \\ 0.3524 & -0.0455 & 1.7775 \end{bmatrix} \mathbf{G}_{SE}^{-1} \\ &= \begin{bmatrix} 0.2642 & -0.3882 & 0.0366 \\ 0.8519 & 1.1689 & -0.0457 \\ -0.0306 & 0.1069 & 0.5542 \end{bmatrix} \end{aligned} \quad (14)$$

The distributions of color errors for fitting respectively on real and synthetic spectra under Illuminant E have means of 0.48 and 0.83 ΔE^*_{ab} , and error percentages of 13.5% and 25.4% above the visibility threshold. Testing the matrix on the real samples gives a mean error of 0.54 ΔE^*_{ab} and 17.1% of errors above the visibility threshold. These error distributions and their statistics are similar to those arising from the linear matrices fitting the same spectra for the transformation of X, Y, Z tristimulus values from the CIE 1931 to CIE 2015 system, as described in the previous section.

Substituting from Eq. (1) into Eq. (9):

$$\begin{bmatrix} \overline{x_{1931}}(\lambda) & \overline{y_{1931}}(\lambda) & \overline{z_{1931}}(\lambda) \end{bmatrix} = \begin{bmatrix} \overline{l}(\lambda) & \overline{m}(\lambda) & \overline{s}(\lambda) \end{bmatrix} \mathbf{F} \mathbf{M}_R \quad (15)$$

Comparing Eq. (12), it follows that:

$$\mathbf{G} = \mathbf{F} \mathbf{M} \quad (16)$$

To verify this numerically, for real samples under equi-energy illumination we have from Eqs. (6), (11) and (13):

$$\begin{aligned} \mathbf{M}_{RE} &= \begin{bmatrix} 0.9287 & -0.0451 & -0.0525 \\ 0.0096 & 1.0064 & 0.0664 \\ 0.0077 & -0.0165 & 0.9360 \end{bmatrix} \mathbf{F}_{RE} \\ &= \begin{bmatrix} 1.9474 & 0.6899 & 0 \\ -1.4145 & 0.3483 & 0 \\ 0.3648 & 0 & 1.9349 \end{bmatrix} \end{aligned}$$

$$\mathbf{M}_{RE} = \begin{bmatrix} 1.8151 & 0.6064 & -0.0565 \\ -1.3102 & 0.4144 & 0.0974 \\ 0.3537 & -0.0483 & 1.7919 \end{bmatrix}$$

$$\mathbf{M}_{RE} * \mathbf{M}_{RE} = \begin{bmatrix} 1.8151 & 0.6065 & -0.0564 \\ -1.3103 & 0.4143 & 0.0974 \\ 0.3537 & -0.0484 & 1.7919 \end{bmatrix}$$

Transformation Under Illuminant D65

The calculations above for transformation of L, M, S to X, Y, Z were all made for Illuminant E (equi-energy) with no normalization. Repeating for Illuminant D65 (standard daylight) gives different transform matrices. Without normalization, the white responses are:

$$(1931) [X_w, Y_w, Z_w] = [100.43, 105.67, 115.03]$$

$$(2015) [X_w, Y_w, Z_w] = [105.85, 111.71, 120.13]$$

$$(LMS) [L_w, M_w, S_w] = [113.04, 96.81, 62.09]$$

Regression fitting over the set of real samples under D65 yields:

$$\begin{aligned} \mathbf{G}_{R65} &= \begin{bmatrix} 1.8145 & 0.6080 & -0.0623 \\ -1.3100 & 0.4124 & 0.1025 \\ 0.3578 & -0.0491 & 1.8150 \end{bmatrix} \mathbf{G}_{R65}^{-1} \\ &= \begin{bmatrix} 0.2653 & -0.3874 & 0.0310 \\ 0.8499 & 1.1672 & -0.0368 \\ -0.0293 & 0.1080 & 0.5439 \end{bmatrix} \end{aligned} \quad (17)$$

Regression fitting over the set of synthetic samples under D65 yields:

$$\begin{aligned} \mathbf{G}_{S65} &= \begin{bmatrix} 1.8133 & 0.6112 & -0.0784 \\ -1.3082 & 0.4072 & 0.1280 \\ 0.3567 & -0.0463 & 1.8014 \end{bmatrix} \mathbf{G}_{S65}^{-1} \\ &= \begin{bmatrix} 0.2626 & -0.3898 & 0.0391 \\ 0.8531 & 1.1700 & -0.0460 \\ -0.0301 & 0.1072 & 0.5462 \end{bmatrix} \end{aligned} \quad (18)$$

The distributions of color errors for fitting respectively on real and synthetic spectra under D65 have means of 0.47 and 0.80 ΔE^*_{ab} , and error percentages of 12.7% and 24.3% above the visibility threshold, all of which are slightly smaller

Transformation of Color Matching Functions, Fig. 5 Spectral power distribution of the primaries of a CRT display [4]

than for Illuminant E. Testing the matrix on the real samples gives a mean error of $0.52 \Delta E^*_{ab}$ and 16.1% of errors above the visibility threshold.

The computation procedure above could also be applied for other observers, for example, individuals whose color matching functions differ from the CIE Standard Observer, or for a camera or scanner or other instrument with known spectral sensitivity in each channel. They could also be applied for any illumination spectrum, from which it would follow that a best-fitting matrix could be found to transform the tristimulus values from any illuminant A to illuminant B, for a given observer. This would provide the basis for prediction of chromatic adaptation between differing illumination of known spectra.

Transforming Stimuli from Displays

When colors are produced by a display, the scenario is different from above because the

visual stimuli are emitted by three specific primaries, rather than being reflected from a surface illuminated by some source of light. For a CRT display, these are determined by the characteristic R, G, B phosphor spectra, such as those in Fig. 5.

The transformation from linear light R, G, B to tristimulus values X, Y, Z can be represented as:

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} X_r & X_g & X_b \\ Y_r & Y_g & Y_b \\ Z_r & Z_g & Z_b \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix} = \mathbf{RGB_XYZ} \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (19)$$

where X_r is the contribution to X of the red primary, calculated as $X_r = \sum R(\lambda)X(\lambda)$, etc.

Similarly, the transformation from linear light R, G, B to cone responses L, M, S can be represented as:

$$\begin{bmatrix} L \\ M \\ S \end{bmatrix} = \begin{bmatrix} L_r & L_g & L_b \\ M_r & M_g & M_b \\ S_r & S_g & S_b \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix} = \mathbf{RGB_LMS} \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (20)$$

from which it follows that:

$$\begin{aligned} \mathbf{RGB_XYZ}^{-1} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} &= \begin{bmatrix} R \\ G \\ B \end{bmatrix} \\ &= \mathbf{RGB_LMS}^{-1} \begin{bmatrix} L \\ M \\ S \end{bmatrix} \end{aligned} \quad (21)$$

Hence:

$$\begin{aligned} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} &= \mathbf{RGB_XYZ} \cdot \mathbf{RGB_LMS}^{-1} \begin{bmatrix} L \\ M \\ S \end{bmatrix} \\ &= \mathbf{LMS_XYZ} \begin{bmatrix} L \\ M \\ S \end{bmatrix} \end{aligned} \quad (22)$$

Using the same scaling of X, Y, Z and L, M, S as in the previous sections, the matrices are computed as:

$$\begin{aligned} \mathbf{RGB_XYZ} &= \begin{bmatrix} 1.8113 & 0.4821 & 2.1926 \\ 1 & 1 & 1 \\ 0.1098 & 0.1923 & 11.1304 \end{bmatrix}, \\ \mathbf{RGB_LMS} &= \begin{bmatrix} 0.8373 & 0.6075 & 0.6604 \\ 0.2013 & 0.4169 & 0.6141 \\ 0.1090 & 0.1693 & 11.5769 \end{bmatrix} \end{aligned} \quad (23)$$

and so:

$$\begin{aligned} \mathbf{XYZ_LMS} &= \begin{bmatrix} 0.2745 & 0.8466 & -0.0352 \\ -0.3830 & 1.1655 & 0.1032 \\ 0.0100 & -0.0208 & 0.5429 \end{bmatrix}, \\ \mathbf{LMS_XYZ} &= \begin{bmatrix} 1.8072 & -1.3061 & 0.3653 \\ 0.5948 & 0.4253 & -0.0423 \\ -0.0105 & 0.0404 & 1.8335 \end{bmatrix} \end{aligned} \quad (24)$$

Transformation of Color Matching Functions, Fig. 6 LMS cone fundamentals expressed in units of luminance

Note that the original cone spectral sensitivities were scaled to unity (Fig. 4). To express them in luminance units, the scaling factors given by Stockman and Sharpe need to be applied. The cone response functions are multiplied by the respective scaling factors:

$$k_L = 0.624899, k_M = 0.416602, k_S = 1.915443 \quad (25)$$

The scaled cone response functions then appear as in Fig. 6.

The transform and its inverse in Eq. (24) change to the following:

$$\begin{aligned} \mathbf{XYZ}_{\text{LMS}} &= \begin{bmatrix} 0.1716 & 0.5290 & -0.0220 \\ -0.1595 & 0.4855 & 0.0430 \\ 0.0191 & -0.0399 & 1.0399 \end{bmatrix}, \\ \mathbf{LMS_XYZ} &= \begin{bmatrix} 2.8919 & -3.1352 & 0.1907 \\ 0.9518 & 1.0208 & -0.0221 \\ -0.0167 & 0.0969 & 0.9572 \end{bmatrix} \end{aligned} \quad (26)$$

These equations are different from Eqs. (13) and (14), because the viewing environment involves color stimuli generated by a CRT display. All stimuli in this case are weighted combinations of the spectra of the three primaries, modulated by the signal level. It is assumed that the device is linear and additive, with no cross-talk between channels and with negligible ambient illumination, thus making possible the simple formulation in Eqs. (19) and (20).

One could imagine a different scenario in which the display white was used as the light source to illuminate a series of reflective samples with known reflectance spectra, but in this case the light reaching the eye for each sample would consist of the display white spectrum multiplied by the reflectance spectrum of the surface. This would lead through regression to a different transformation matrix. A display with white balance matched to D65 is metameric to a daylight spectrum correlated to 6500 K.

The method given above in Eqs. (19) to (26) could be applied to any display technology, such as LCD or LED, provided that the device is additive and free from cross-talk. All that is required is to measure the spectra of the three primaries.

Transient Imaging

Adrian Jarabo

Graphics and Imaging Lab, Universidad de Zaragoza, I3A, Zaragoza, Spain

Synonyms

Femto-photography; Light-in-flight imaging; Ultrafast Imaging

Definition

Transient imaging refers to the set of techniques within the field of computational imaging that focus on capturing and analyzing the propagation of ultrashort light pulses and its interaction with matter, at frame rates comparable to the speed of light. It allows to capture the optical impulse response of a scene as a function of time. This has multiple applications in scene understanding and computer vision, including range imaging, non-line-of-sight reconstruction, vision through turbid media, BRDF estimation, or light-in-flight imaging.

Transient State Versus Steady State

One of the most general assumptions in computer vision and scene understanding is to consider the speed of light to be infinite, therefore assuming light transport in steady-state. This is a reasonable assumption since most of the existing imaging hardware is very slow compared to the speed of light. Even in the case of high-speed cameras, capable to capture up to a few thousands of frames per second, light travels tens of kilometers in each frame (Fig. 1, left). With the emergence of ultrafast imaging devices, effective exposure times of nano- or picoseconds have been made possible. At such exposure times, light travels a few centimeters per frame, effectively breaking the assumption of steady state of light, requiring to account for the time-resolved nature of light transport. Light $L(x, t)$ incoming at the camera's pixel x is a function defined on the temporal domain

t (Fig. 1). This time-resolved radiance relates with its steady-state counterpart $L_s(x)$ as:

$$L_s(x) = \int_{-\infty}^{\infty} L_t(x, t) dt. \quad (1)$$

Breaking the steady-state assumption has led to many promising applications in computer vision and scene understanding, including robust range imaging, non-line-of-sight reconstruction, vision through turbid media, or reflectance recovery.

Historical Development

Ultrafast imaging of impulse illumination in macroscopic scenes was first proposed in the 1970s by Abramson [1]; he proposed to use holography, achieving femtosecond temporal resolution. However, Abramson's technique was based on light coherence. Therefore, it focused in direct illumination, resulting in the loss of indirect illumination. Ultrafast imaging of direct illumination has been an active field on its own for decades, given its importance for range imaging for, e.g., robotics, remote sensing, or 3D scanning. In this context, two main technologies stand out: LiDAR (*light detection and ranging*), which measures distance by taking into account the light time of flight from an ultrashort laser pulse to the camera; and *time-of-flight* (ToF) cameras that use coded illumination and sensor for sensing depth. These two technologies focused on depth imaging, rather than capturing light in flight; more details on range sensors can be found in [5].

The first system capable of imaging light in motion at large spatial and temporal resolution

Transient Imaging, Fig. 1 Synthetic example of time-resolved light transport. In steady state (left), all light has finished propagating along the scene. In transient state, however, the radiance incoming at pixel is a function of

time, and light takes several nanoseconds to finishing propagating along the scene. The plot shows the temporal profile of radiance in pixel (a), while the individual frames are shown as blue dashed lines in the plot

was Velten et al.'s *femto-photography* [14]. They proposed to combine an ultrafast sensor with femtosecond laser, to capture videos at picosecond resolution of light in motion, including indirect illumination or multiple scattering. Inspired by this system, many other works have been proposed, either developing cheaper, more robust capture systems [3, 6], reducing the amount of measurements by single-shot transient imaging using compressed sensing [2], or significantly increasing the temporal resolution by using optical time-stretching via dispersive optics [11].

In the following, the different approaches for capturing transient light transport are described, as well as some of the most promising applications of this technology. An in-depth discussion can be found in recent surveys on the topic [8].

Capturing Light in Flight

Imaging light in flight is equivalent to capture the impulse response of a scene along the temporal domain. The impulse response of a scene is a linear operator that relates the scene illumination with the captured image, via the light transport equation:

$$\mathbf{i}(t) = \int_{-\infty}^{\infty} \mathbf{T}(\tau) \mathbf{p}(t - \tau) d\tau = (\mathbf{T} * \mathbf{p})(t), \quad (2)$$

where $\mathbf{i}(t)$ is the spatio-temporal image, $\mathbf{p}(t)$ is the time-resolved illumination function, and $\mathbf{T}(t)$ is the light transport matrix describing the light transport with a time-of-flight of exactly t . The second equality represents the convolution in the temporal domain between $\mathbf{T}$ and $\mathbf{p}$. The ideal case for obtaining $\mathbf{T}(t)$ in a scene is to use a delta illumination in the temporal domain. However, this is in general expensive, and different cheaper approaches have been proposed for capturing $\mathbf{T}(t)$. These systems can be categorized in three main categories:

1. Straight Temporal Recording

This is the conceptually simplest approach and consists on using pulsed illumination and ultrafast imaging hardware to capture Eq. (2).

Several different optical systems have been proposed, including streak-cameras [14], single photon avalanche diodes (SPAD) [3], or dispersive optics combined with white-light lasers [11]. These systems range in terms of cost, temporal resolution, operating time, or spatial resolution: For example, while SPADs are cheap, they have limited spatio-temporal resolution; streak-cameras, on the other hand, are expensive, difficult to operate, and need long capture times but have large spatial resolution, and effective exposure times in the order of 2 picoseconds.

2. Interferometry

Interferometry was the first technology for imaging light in motion [1], although its limited range of applicability has made its scope relatively narrow. The key idea is to leverage electromagnetic interference of coherent light to disambiguate between slightly different path lengths. This results into a very high temporal resolution (at the femtosecond scale), at the price of working in small scenes and losing incoherent light such as indirect illumination.

3. Phase-Based Time-of-Flight Cameras

The last type of systems used for transient imaging base on phase-based time-of-flight (P-ToF) cameras is called correlation-based time-of-flight (C-ToF) or simply ToF cameras [5]. These are the cheapest systems of the three and were designed for low-cost time-of-flight-based range imaging with high spatial resolution. P-ToF cameras cross-correlate emitted time-modulated light and the sensor response with (generally) a periodic continuous wave. This correlation encodes the impulse response of a pixel modulated at the sensor. By using a small set of measurements with different phase-shifts, it allows to disambiguate light time-of-flight. Beyond range imaging, Heide and colleagues [6] demonstrated that by taking several measurements with different modulation frequencies and phase shifts, it was possible to reconstruct transient images using optimization, leading to low-budget transient imaging using easy-to-operate hardware. The main drawback of these systems is the

Transient Imaging, Fig. 2 Example frames of light-in-flight visualizations captured by using (from left to right) straight temporal recording (femtophotography [14]), interferometry [4], and phase-based ToF cameras [6]. Each device has its different capabilities and range of

applicability, being able to capturing scenes with different scales, and imposing a temporal resolution of up to around 1–2 ps (straight recording), 30 fs (interferometry), and 1 ns (ToF cameras). Full visualizations of the captured data can be found in the respective sources

significantly lower temporal resolution, compared with the two alternative approaches.

Figure 2 shows example frames of light-in-flight visualizations of captured transient data using each of these three approaches.

Applications

Time-resolved data has opened up a wide set of applications. Long-standing problems in computer vision like depth recovery or vision through turbid media, to name a few, have received renewed attention in light of this new data. Novel applications on scene understanding have additionally emerged thanks to the additional information encoded in time-of-flight data, including robust range imaging in the presence of interreflections and scattering media, material estimation, global illumination separation, light-in-flight imaging, or non-line-of-sight reconstruction of hidden scenes. The most relevant applications are described in the following:

Range Imaging

Range imaging aims to recover the depth information from a scene and is a key problem in computer vision. While several approaches have been proposed to tackle the problem (including stereo and multiview reconstruction or structured illumination), transient-based range imaging is one of the most successful approaches. Intuitively, the idea is to measure the time (and consequently

the distance traveled) that takes a light pulse to travel from a calibrated emitter source to the sensor, so that the first incoming response of the scene encodes the depth at a pixel. This is the main application for transient image for decades, in particular for LIDAR or time-of-flight sensors [5]. However, these techniques are sensitive to errors produced by **multipath interference** (MPI), where light from multiple light paths affects the range measurement of direct illumination, resulting in errors. This type of errors might be problematic in the case of indirect illumination from nearby geometry but is completely pathological for imaging through turbid media, where MPI dominates. Capturing the full temporal response has allowed to disambiguate direct and indirect illumination, as well as the contribution of media. This has resulted into significantly more robust depth estimation techniques (e.g., [15]), even in the presence of scattering media using cheap ToF sensors [7].

Material Estimation and Classification

Time-resolved data gives valuable information on the optical properties of surfaces and media, given the particular time profiles of light-matter interactions. For example, fluorescence lifetime imaging allows to measure the reemission response of fluorescent materials even through turbid media and uses this response to detect and classify such materials. The temporal response has been also used to capture the optical properties of translucent objects and use them for classification, based on the reflectance decay in the temporal domain

Transient Imaging, Fig. 3 Left: Canonical setup for NLOS imaging, where a hidden object is recovered from indirect reflections in a visible relay wall. Middle: While this technology has enormous potential in several applications, most methods have managed to capture only small, isolated objects in carefully controlled laboratory

conditions [13]. Right: The applicability of NLOS imaging has significantly increased recently, with the development of *phasor fields* [9], which allow reconstructing large scenes with arbitrary geometrical complexity and materials. The insets show the scenes to be reconstructed

[15]. Finally, the ability of demultiplex light paths along its path length has been used for creating virtual gonireflectometers for capturing materials reflectance.

Non-line-of-Sight Imaging

Non-line-of-sight (NLOS) imaging aims to recover objects that are not directly in the line of sight of the observer [10]. It is generally known as “looking around corners,” although its range of applications goes beyond these scenarios. The key idea is to use the indirect reflections on a secondary visible wall to reconstruct the hidden scene (see Fig. 3, left). It was first demonstrated by the seminal work by Velten and colleagues [13], who used a setup similar to *femto-photography* [14] for reconstructing hidden simple tabletop scenes. The problem has gained significant attention over the last few years, leading to significant advances allowing to use cheaper sensors and demonstrated real-time performance [12]. Most works in this field have assumed very simplistic scenes, with simple isolated objects with small contribution from high-order scattering, and simplistic materials (Fig. 3, middle). Most recently, NLOS imaging was proved to work on more challenging conditions, including scenarios with significant complexity and range, arbitrary materials, and significant MPI, by posing the inverse problem as a virtual forward light transport model [9] (Fig. 3, right). This has allowed to use knowledge

from traditional Fourier optics into the NLOS domain, which might lead to many novel applications in NLOS imaging in general.

Transition Metal Ion Colors

Richard J. D. Tilley
Cardiff University, Cardiff, UK

Synonyms

d-Block elements

Definition

Transition metals are d-block elements with partially filled 3d, 4d, and 5d orbitals.

Color Production

The transition metals are (somewhat imprecisely) described as being colored because their compounds frequently take on a characteristic hue (Table 1). For example, Ni^{2+} cations tend to exhibit green coloration, while Cu^{2+} tends to show green-blue tones. Cobalt, as Co^{2+} , has been used since medieval times to color glass deep blue, and small amounts of impurity Cr^{3+} in colorless Al_2O_3 produce the color in ruby gemstones (Fig. 1). All these colors arise from electronic transitions between the ionic ground state and energy levels lying between 1.77 and 3.10 eV above it, giving absorption maxima in the visible wavelength range (400–700 nm). These low-lying energy levels arise from interactions of the d orbitals on the cation with neighboring atoms in a material and are a function of the symmetry of the surroundings [1–3]. The energy levels that occur with the 4d and 5d transition metals are higher in energy than those of the 3d series and are of lesser importance in color terms. In this entry, only the 3d transition metal ions are covered and, in addition, only single dopants are considered. (When two or more transition metal ion impurities are present, an alternative mechanism, charge transfer, can also lead to coloration.)

Electronic Energy Levels

Energy Levels and Terms

The energy levels of a free transition metal cation are dominated by electron–electron repulsion and are described by *term symbols*. A *term* is a set of states which are very similar in energy. Transitions between terms, or, more precisely, the energy levels specified by the term, give rise to the observed line spectrum of the free ion. The terms of an ion can be derived by Russell–Saunders (*LS*) coupling [2, 4]. In this designation, each term is written as ^{2S+1}L where L is a many-electron quantum number describing the total orbital angular momentum of the electrons surrounding the atomic nucleus and S is a many-electron quantum number representing the total electron spin. The superscript $(2S + 1)$ is called the *multiplicity* of the term. The total angular

Transition Metal Ion Colors, Table 1 Typical 3d transition metal ion colors

Cu ²⁺ d ⁹	Green Blue	Octahedral ^a Octahedral ^a	Cu ₂ (OH) ₂ (CO ₃) (malachite) Cu(H ₂ O) ₆ ²⁺ in solution and hydrates

^aNote that the octahedral coordination in Cu²⁺ compounds is often distorted with (usually) two long axial bonds and four shorter equatorial bonds, to the extent that the coordination polyhedron is often described as square planar

Transition Metal Ion Colors, Fig. 1 Synthetic ruby spheres consisting of colorless Al₂O₃ doped with trace amounts of Cr³⁺

momentum quantum number L is given a *letter symbol*, S ($L = 0$), P ($L = 1$), D ($L = 2$), and F ($L = 3$), and thereafter alphabetically, omitting J. The energies of the terms must be determined

by quantum mechanical calculations, except for that of the ground state, which is given by Hund's second rule: the ground state is the term with the highest multiplicity and, if more than one term of the same multiplicity is present, by that with the highest L value. The low-energy terms of free 3d transition metal cations are given in Table 2.

Crystal Field Splitting

When a cation is placed into a crystal, the d electrons interact with the surrounding anions and give rise to new energy states. The simplest conceptual model that describes the formation of the color-producing energy levels is called *crystal field theory* [5, 6]. In this approach, the electrostatic effect of neighboring anions upon the energies of the cationic d orbitals is considered in terms of surrounding point charges. More comprehensive treatments, which include the effects of covalent bonding, fall into the domain of *ligand field theory* [7, 8], although the two expressions are often used interchangeably.

The d orbitals on a 3d transition metal cation can be described as pointing along or between a set of x-, y-, and z-axes (Fig. 2). The orbitals directed between the axes are the d_{xy} , d_{yz} , and d_{xz} set, and

Transition Metal Ion Colors, Table 2 Low-energy terms of free 3d transition metal cations

^aGround state term **bold**

those pointing along the axes are the $d_{x^2-y^2}$ and d_{z^2} pair. If electron–electron interactions are ignored, all of these orbitals are degenerated (have the same energy). However, this is not true when the ion is placed into a crystal because of the interaction (most easily imagined as repulsion) between the electrons on the surrounding ions and the electrons occupying d orbitals. If the surrounding charges are distributed evenly over the surface of a sphere, the five d orbitals are still energetically degenerated, although at a higher energy by an amount E_0 . In a crystal the charges are not smeared out but arranged in a pattern. This removes the degeneracy and gives rise to a new set of energy levels (Fig. 3). The pattern of this *crystal field splitting* depends upon the symmetry of the surrounding anions.

The two most important geometries to consider, especially for oxide pigments and ceramics, are octahedral and tetrahedral coordination

Transition Metal Ion Colors, Fig. 2 Electron density lobes of the d orbitals

Transition Metal Ion

Colors, Fig. 3 Change of d-orbital energies when a free ion is introduced into a crystal (schematic)

Transition Metal Ion Colors, Fig. 4 (a) Octahedral and (b) tetrahedral coordination geometry. A cation is at the cube center. In (a) anions are at the center of each face. In (b) four anions occupy half the cube corners

(Fig. 4a, b). When a cation is surrounded by six anions arranged at the vertices of a regular octahedron, the $d_{x^2-y^2}$ and d_{z^2} orbitals point directly toward the surrounding anions and are raised in energy more than the d_{xy} , d_{xz} , and d_{yz} trio, which point between the anions. This splits the originally degenerated energy levels into two groups. The higher energy state, labeled e_g , consists of two equal energy levels, derived from the $d_{x^2-y^2}$ and d_{z^2} orbitals. The lower energy state, labeled t_{2g} , consists of three equal energy levels, derived from the d_{xy} , d_{xz} , and d_{yz} orbitals (Fig. 5). The energy gap between the t_{2g} orbitals and the e_g orbitals is written Δ or $10Dq$, with the t_{2g} set at $-4Dq$ and the e_g set at $+6Dq$ with respect to the spherically symmetrical situation. When Δ is small, the crystal field is said to be *weak*, and when large it is referred as *strong*. Strong crystal fields arise from ions with multiple charges and relatively short

cation–anion spacing, together with contributions due to covalent bonding.

When a cation is surrounded by a tetrahedron of anions, the crystal field splitting found for octahedral coordination is reversed. In this case, the higher energy group, now labeled t_2 , is derived from the d_{xy} , d_{xz} , and d_{yz} orbitals, and the lower energy group, now labeled e , is derived from the $d_{x^2-y^2}$ and d_{z^2} orbitals. The t_2 set is at $+4Dq$ and the e set is at $-6Dq$ with respect to the spherically symmetrical situation (Fig. 5). The magnitude of Δ for tetrahedrally coordinated cations is $4/9$ of that for the same cation when octahedrally coordinated.

Term Splitting

The electronic energy levels of a free transition metal ion arise from electron–electron interactions, and the simple model just outlined must be

Transition Metal Ion Colors, Fig. 5 Splitting of d-orbital energy levels in a crystal field: octahedral and tetrahedral symmetries

Transition Metal Ion Colors, Table 3 Splitting of terms in fields of cubic symmetry

Free ion term	Terms in tetrahedral crystal field	Terms in octahedral crystal field
S	A_1	A_{1g}
P	T_1	T_{1g}
D	E, T_2	E_g, T_{2g}
F	A_2, T_1, T_2	A_{2g}, T_{1g}, T_{2g}
G	A_1, E, T_1, T_2	$A_{1g}, E_g, T_{1g}, T_{2g}$

adapted so as to apply to the free ion terms. It is found that a term may split into several energy states when the cation is subjected to the crystal field. The number of states that arise is a function of the value of L and the symmetry of the surrounding neighboring anions (Table 3). The magnitude of the splitting is a function of the anion–cation separation and the charges on the ions involved. The multiplicity of the term is carried over onto the new states. The energy states in the crystal are given labels that describe the degeneracy of the orbitals: A is a singly degenerate state, E represents a doubly degenerate state, and T represents a triply degenerate state. Different configurations of sets of orbitals with the same degeneracy are labeled with subscripts 1, 2, and so on. Thus a P term gives rise to a T_1 term, while a D term gives rise to a T_2 term. The subscript “g” means a center of orbital symmetry exists. The energy of the new states needs to be calculated

using quantum mechanical methods or determined experimentally from spectra.

Selection Rules

Electron transitions are governed by selection rules that give the *probability* that a transition will occur. Transitions between d orbitals are forbidden by the Laporte selection rule. However, this rule may break down for ions in compounds. The main reason for this is a degree of mixing between s, p, and d orbitals can occur when an ion is not located at a center of symmetry. As s or p to d transitions are allowed, transitions giving rise to color are also allowed, to a degree corresponding to the amount of orbital mixing achieved. Thus ions situated in tetrahedral coordination, which are not at a center of symmetry, show quite strong colors. Ions at the center of a perfect octahedron are at a center of symmetry, and color-producing transitions are forbidden, but in most solids and liquids, thermal agitation of the surroundings and crystal distortions remove the precise symmetry, making such transitions weakly allowed. As a consequence, they are often less intense than those from similar ions in tetrahedral sites.

In addition, transitions are only allowed between states of the same multiplicity, called *spin-allowed transitions*. Transitions between states of differing spin can be weakly allowed in some circumstances, but in general these do not give rise to strong colors.

The Color of 3d Transition Metal Ions

Color and Term Splitting

Using Tables 2 and 3, a qualitative energy level diagram can be readily constructed for the splitting of the ground state terms (Fig. 6). It is seen that the arrangement of the energy levels is symmetrical about the d^5 (6S) term. The splitting for a d^n ion in an octahedral field is the same as that for a d^{10-n} ion in a tetrahedral field. Recall, though, that the magnitude of the splitting for cations in a

tetrahedral field is $4/9$ of that in an octahedral field. The colors exhibited by many transition metal ions can now be understood.

Figure 6 indicates that octahedrally coordinated d^5 ions (Fe^{3+} , Mn^{2+}) exhibit no ground state crystal field splitting and are not expected to show any colors. This is so, and compounds of these ions are at best weakly colored due to other factors. The free ion ground state of octahedrally coordinated d^1 ions (Ti^{3+} , V^{4+}), d^4 ions (Cr^{2+} , Mn^{3+}) d^6 ions (Fe^{2+}), and d^9 ions (Cu^{2+}) splits into two, and these ions will

**Transition Metal Ion Colors, Fig. 7** The absorption spectrum of Cu²⁺(H₂O)₆

show one absorption band, corresponding to a transition between these two energy levels. If all or part of this band is in the visible, compounds containing these cations will show color (Table 4). For example, the spectrum of (approximately) octahedrally coordinated Cu²⁺ in Cu²⁺(H₂O)₆ has a single absorption band in the infrared, with a peak at approximately 780 nm (Fig. 7), but this extends into the visible, resulting in absorption of red and orange, with a result that the solution takes on the characteristic Cu²⁺ blue-green color.

The situation with the ions d² (V³⁺), d³ (Cr³⁺), d⁷ (Co²⁺), and d⁸ (Ni²⁺) is not so simple. Figure 6 indicates that these should show two transitions,

but the experimental data (Table 4) makes it clear that three transitions are observed. As transitions giving rise to color are between states of the same multiplicity, for these ions it is necessary to take into account the existence of other terms with the same multiplicity as the ground state. The ions d² (V³⁺), d³ (Cr³⁺), d⁷ (Co²⁺), and d⁸ (Ni²⁺) have two free ion terms of the same multiplicity, ³F ³P for d² and d⁸ and ⁴F ⁴P for d³ and d⁷ (Table 2). In the crystal field, the higher energy ³P or ⁴P states give rise to ³T and ⁴T states (Fig. 8). Spin-allowed transitions to these additional energy levels give rise to three absorption bands in the case of V³⁺, Co²⁺, and Ni²⁺ (Table 4). In Cr³⁺ ions the transition to the ⁴T state is at a high energy and is not recorded in the visible spectrum. These absorption peaks will give rise to colored compounds, but the shade will depend upon the position and relative intensity of the bands. This can be quite variable, as described for Cr³⁺ in the following section.

The Effect of Crystal Field Strength and Other Factors

Although crystal field splitting gives an accurate picture of the number of absorption peaks observed, the actual position of these peaks

Transition Metal Ion Colors, Fig. 8 Splitting of ground state and higher free ion terms with the same multiplicity in a crystal field of octahedral symmetry, schematic. Transitions that give rise to color shown as arrows

depends upon the crystal chemistry of the surroundings, which alters the effective strength of the crystal field. Moreover, the absorption peaks are frequently broad or show shoulders, indicating that the simple description given above is in need of refinement. Here just one example will be given. Octahedrally coordinated Cr^{3+} ions can induce a variety of colors including ruby red, emerald green, and violet. In all cases the color arises from transitions between the $^4A_{2g}$ ground state and the higher $^4T_{2g}$ and $^4T_{1g}$ levels. Ruby consists of colorless corundum (Al_2O_3) crystals with $\sim 0.1\%$ of Cr^{3+} ions occupying octahedral Al^{3+} sites. In this material the absorption peaks are:

$$^4T_{2g} \leftarrow ^4A_{2g}; \text{maximum } 556 \text{ nm; green-yellow}$$

$$^4T_{1g} \leftarrow ^4A_{2g}; \text{maximum } 400 \text{ nm; violet.}$$

The absorption at 556 nm removes green-yellow and the absorption at 400 nm removes violet. Between the absorption curves, there is a relatively small transmission window at approximately 486 nm, and a red transmission window is present at wavelengths greater than 650 nm. This means that the color transmitted by the ruby will be red with something of a blue undertone.

Emerald consists of the colorless mineral beryl with Cr^{3+} impurity ions occupying octahedral Al^{3+} sites. In beryl the octahedra surrounding the Cr^{3+} ions are slightly larger than in corundum, and

so the crystal field experienced by the Cr^{3+} in emerald is weaker than in ruby, causing a shift in the $^4T_{1g}$ and $^4T_{2g}$ levels toward the ground state with the result that the transitions move slightly toward the lower end of the spectrum:

$$^4T_{2g} \leftarrow ^4A_{2g}; \text{absorption maximum } 650 \text{ nm; orange-red}$$

$$^4T_{1g} \leftarrow ^4A_{2g}; \text{absorption maximum } 450 \text{ nm; blue.}$$

The band that absorbs green-yellow in ruby now absorbs orange-red in emerald, and the violet-absorbing band in ruby now absorbs blue. Between the absorption curves, there is a blue-green transmission window at 500 nm. The result of these small shifts is to transform the ruby red into emerald green.

In crystalline chrome alum and water solution, the Cr^{3+} ions are at the center of an octahedron of O^{2-} ions in the complex $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$. The crystal field now gives rise to the absorption bands:

$$^4T_{2g} \leftarrow ^4A_{2g}; \text{absorption maximum } 575 \text{ nm; yellow}$$

$$^4T_{1g} \leftarrow ^4A_{2g}; \text{absorption maximum } 408 \text{ nm; violet.}$$

These bands are positioned so as to emphasize purple violet, the dominant tone of chrome alum.

Although the overall color of transition metal ions in solids is explained by crystal field effects, the eye can detect subtle variations that require more complex explanations. Again ruby serves as an example. In this gemstone, the octahedra that are occupied by the Cr^{3+} ions are distorted, causing the ${}^4\text{T}_{2\text{g}}$ and ${}^4\text{T}_{1\text{g}}$ levels to split due to a change of local symmetry. The separation of the new levels is small but does give a color change that adds to the value of the stones and also produces polarization effects. In addition, an energy level ${}^2\text{E}_{\text{g}}$ (derived from splitting of the free ion ${}^2\text{G}$ term) falls between the ground state and the ${}^4\text{T}_{2\text{g}}$ level. This level is also split in the distorted octahedral sites in these crystals. Although direct excitation to and from the ground state to the ${}^2\text{E}_{\text{g}}$ levels is forbidden by the multiplicity selection rule, it is populated indirectly, and that gives rise to two closely spaced emission lines R_1 at 693.5 nm and R_2 at 692.3 nm in the ruby spectrum. This radiation enhances the color of the best rubies and is made to dominate light emission during ruby laser action.

Color as a Structural Probe

The absorption spectrum of a transition metal ion in a solid can give structural and chemical information that is not easily obtained via other techniques. This is because the absorption spectrum depends upon the local geometry of the site occupied and the valence state of the colored ion. Although this information is sometimes available from X-ray diffraction, in crystals where several cations with more than one valence state may statistically occupy the same site, X-ray diffraction data can be ambiguous. Moreover, the measurement of absorption spectra is diagnostic of the oxidation state of transition metal ion and can be used to infer the local conditions prevailing during formation.

For example, the spinel structure is adopted by many compounds with a formula AB_2O_4 , where A and B are medium-sized cations. In this structure the cations sit in both octahedral and tetrahedral sites. The absorption spectra of transition metal ions are quite different for these geometries, and so the site occupancy can be easily and unambiguously determined. The spinel NiAl_2O_4 is a case in point. The absorption

spectrum of this material reveals that the Ni^{2+} ions are found in both positions. In the related spinel NiGa_2O_4 , the Ni^{2+} ions exclusively occupy octahedral sites.

The problem of site occupancy is more acute in amorphous or disordered materials such as glasses because these structures cannot readily be determined by X-ray crystallography. However, it is often possible to incorporate a small amount of a transition metal into the structure as a probe of local geometry. For example, silicate glasses containing a small quantity of Co^{2+} are colored blue, typical of tetrahedral coordination, indicating that these ions replace Si^{4+} in the glass network. Similarly, small amounts of Mn^{2+} , Co^{2+} , and Fe^{2+} incorporated into a ZnCl_2 glass show that in each case, the absorption spectrum corresponds to that expected from tetrahedrally coordinated ions and indicates that the structure is formed from a random network of linked ZnCl_4 tetrahedral units.

Translation of Color Language

Mari Uusküla

School of Humanities, Tallinn University, Tallinn, Estonia

Synonyms

Color language translation; Color term translation; Color word translation; Glossing; Translation of color terms; Translation of color words

Definition

An action in which a color term or color phrase is converted into the meaning of color sense mutually intelligible to the speakers of two different languages, between different historical stages of one or more languages or, in some rare cases, to the speakers of one and the same native language.

Translation of Color Terms Between Languages

As an interdisciplinary subject, the translation of color language has been addressed in linguistics (cognitive linguistics, psycholinguistics, ethnolinguistics, semantics, and historical linguistics), translation studies, semiotics, social anthropology, philosophy, and some other disciplines. Besides translating between languages, the translation of color language can also refer to translating between different historical phases in one language or between a pair of languages. Translation of color terms can be considered in literal language or figurative language. In some rare cases, one can also allude to intra-linguistic translation, that is, a translation of color language within one language when the speakers of the same language disagree on the borders of color categories, naming the same color inconsistently.

Translation is a meticulous action to be carried out by a person who translates from one language

into another, and therefore, many aspects should be considered: the linguistic and social context, cultural customs and practices. The most common type of translation of color language is indisputably a translation performed in two different languages, either genetically related or not, e.g., English *green* can be translated as *verde* in Italian. In translation studies, the language from which one is translating is also called/labelled the *source language* (English in the previous example) and the language into which one is translating is labelled as the *target language* (Italian in the previous example). Besides being a linguistic concept, color is a cultural concept; therefore, the task of translating a color term into another language frequently poses a linguistic and cultural dilemma to a translator [1].

According to the universalist theory or the so-called Berlin and Kay thesis, color language is relatively similar in all languages as all languages possess a certain number of basic color terms from minimally 2 to the maximum of 12 [2]. Yet, the weak relativist theory maintains that there are divergences in both the number of basic color terms and the focals or best examples to which these color terms refer to [3, 6]. Recent studies have suggested a possible augmentation of the number of basic color terms, for example, in English there are two new candidates, *lilac* and *turquoise*, enlarging the number of basic color terms in English to 14 [4].

The question of the translation of color terms was already posed in the original study by Berlin and Kay, but from a different perspective. Berlin and Kay concluded from their examination of 98 languages that the words of color “translate too easily among various pairs of unrelated languages,” which supported the foundation of linguistic universals in the society where the “extreme linguistic relativity” prevailed [5]. However, a significant body of research has challenged the claim of effortless translation between languages, indicating several inconsistencies in mapping color terms into the system of another language, especially between the languages which carve up the color space differently, e.g., Berinmo with its 5 basic color terms and English with at least 11 [3, 6].

Moreover, English has only one color term to designate the blue area of the color spectrum, and therefore, one basic color term for blue. Russian or Italian, on the contrary, both have two to three basic color terms, covering the same area of the color spectrum as the English blue. This complicates the task in which one has to translate the English *blue* into Russian or Italian. The English *blue* might correspond to either *sinij* or *goluboj* in Russian and *blu*, *azzurro*, or *celest*e in Italian [7, 8]. In the classic example, Louis Hjelmslev compares the alignment of color terms in English and Welsh. Namely, the Welsh term *glas* covers parts of *green*, *blue*, and *gray* in English [9]. The Welsh term *gwyrd*d can only be used for parts of green, not the whole green spectral area in English. Therefore, English *green* can either convert into Welsh as *glas* or *gwyrd*d. Translators must be aware of these cases and bring the right terms in line to perform a correct translation. Ardener [10] elucidates the classic example first published by Hjelmslev of how the Welsh speakers divide color categories by comparing Standard Welsh and Modern Colloquial Welsh with English and Igbo, as all these languages carve up the color space differently – five English color categories are translated into four color categories in Standard Welsh and only into two categories in Igbo (Table 1 adapted from Ardener). The key here probably lies in the aspect that hue-based categories (English, Modern Colloquial Welsh) are translated into brightness-based categories (Standard Welsh and Igbo) [6, 11].

As important as the translation of basic color terms between languages may seem, the translation of color language does not only include the

translation of basic color terms but also encompasses the translation of nonbasic color terms. Basic color terms constitute only a small part of color language, and therefore, translatable words often belong to the category of nonbasic color terms [13, 14]. In particular, translation of nonbasic color terms and expressions might pose a more challenging task than finding appropriate equivalent to basic color terms in a target language. This should be taken into account in performing translation from one language into another, especially if the number of basic color terms in the given language pair diverges. In order to offer adjacent translation of color terms in target and source languages, one should ideally research color terms in both languages, finding out about their semantics, lexical and morphological potentials, and the context in which color terms usually appear [12–15].

One possibility to perform translation is to look up the meaning of a color word in another language in a dictionary. However, dictionary entries might not include extensive information on all nuances of color terms and thus, the usage of dictionaries in translation of color terms should be considered with care. Tavast and Uusküla used probabilistic weighting model to account for the better translation options between Italian and Estonian and Spanish and Estonian, also retrieving information from color-naming studies, instead of relying solely to dictionary entries [15]. The problem with dictionary entries is often twofold. First, dictionary definitions might result in inconsistencies and inaccuracies, because they intend to use the basic color terms in order to point to certain objects which might be better described with nonbasic color terms, e.g., “red is the color of blood or fire” where none of these objects actually refer to the red hue but are used metonymically. Often equivalents follow orthographic similarities across languages or through homography, neglecting the actual color sense. Second, it is usually impossible to include color samples as links to certain definitions in dictionaries, especially in printed versions of dictionaries. Thus, color term definitions might remain vague or inconsistent [13]. On the other hand, metonymical expressions such as *raspberry red* or *tulip red*

Translation of Color Language, Fig. 1 Color terms of blue area of the color spectrum in Italian and English as represented in dictionaries [15]. The edges of the graph represent the number of dictionaries in which a certain relationship between the two words was found: the wider the edge, the more this translation version was found in dictionaries

should translate well between the languages, provided that two languages under examination have the same species or raspberries or tulips. A better approach to interpret color terms in two different languages may be to include concepts (colors themselves if possible) into the scheme. Figure 1 represents color translations performed with the help of dictionary entries.

Comparative or contrastive studies between different language pairs provide more substantial information about the meaning of color terms than dictionary entries ever can as they also study the semantic field, lexical and morphological potentials, and context-related information of certain color terms. Philip has comparatively studied the meaning of color terms in Italian and English [16], Jones has published a substantial overview of German color terms with all aspects of their meaning, usage, and historical information which surely facilitates the translation of German color terms into any other language [17].

Kim and colleagues conducted a color-naming experiment using color samples in order to train the computer to provide better translation equivalents in 14 languages instead of widely used online translation tools such as Google translate [18]. They argue that their algorithms are able to

take into account perceptual similarity of the colors matching with color terms in the source and target language. Similarly to Tavast and Uusküla, Kim and colleagues also hint to a possibility to use visualization tools in the future.

Translation of Color Terms Between Different Stages of Language(s)

Translation of color language can also refer to alignment of color terms between different eras or different historical stages of one or more than one languages. This can take place, as in synchronic translation, between two different languages (e.g., Latin and Italian) or across different phases of one language (e.g., Old English and Modern English) or even be restricted to one phase of a certain language (Modern English). In two first cases (Latin to Italian and Old English to Modern English), we find more references to *etymology* than translation in the literature. Translation between different eras can be an extremely difficult task for translators as they need to have substantial knowledge of the context of the historical language. The most difficult are the cases in which there are no written documents of a historical stage of a language from which one is “translating” color language into the present sense. The researcher who is “translating” the color terms in the past to the current variety of a language will benefit from having a dictionary which provides large number of examples in historical texts with the dates of the earliest and the latest occurrences. It is also important to study the lexical, morphological, and syntactic patterns and changes in the past and current versions of a language [12]. According to Biggam, it always depends whether the color system is based on hue, lightness/darkness, or other aspects of appearance. Specific problems can be targeted in the later stages of languages, because we possess more information about the language and the culture if we have more written sources. Table 2 presents all possible Latin equivalents to Old English *græg* (Modern English *gray*) and their possible meaning is Latin [12, 19]. There are altogether eight possible translations to Old English *græg* in

Translation of Color Language, Table 2 Latin translations of Old English *græg* ([19]: 36)

Old English	Modern English	Latin translation	The meaning of Latin translations
<i>græg</i>	<i>gray</i>	<i>cinereus</i>	Ash-gray, ashen
		<i>croceus</i>	Saffron-colored, yellow (or ruddy)
		<i>cycnēus</i>	Swan-like (in whiteness)
		<i>elbus</i>	Dull yellow, gray or brown
		<i>ferrūgineus</i>	Color of rust, purple or black; iron-colored, gray
		<i>ferrūgō</i>	Color of rust, purple or black; iron-colored, gray
		<i>fuscus</i>	Dark-colored; (of person) dark-skinned; gray; obfuscated, opaque
		<i>glaucus</i>	Gray, grayish-blue, silvery-gray; shiny, sparkling, brilliant; grayish-yellow, yellow or orange

Latin. Apparently, the meaning of Old English *græg* has been wider from the color sense of *gray* in Modern English, containing not only grays, but expanding the color sense of the color term considerably.

“Translation” of Color Terms Within One Language

The Berlin and Kay tradition predominantly considers color language without variation of its speakers. However, multiple studies have referred to differences in color lexicon of males and females, mono-, bi-, and multilingual speakers, older and younger speakers of a language, as well as native speakers living in the cities or countryside [12]. Those variations between the speakers of the same native language, having different social, educational, and economic backgrounds, can sometimes be indicated to as intra-linguistic translation or translation of color terms within one language and within one community. Intra-linguistic translation can also refer to inconsistencies, even disagreement of color categories within one linguistic community. In most European languages, there may be vast inconsistencies on whether the same area of color spectrum could be called green or blue – that depends on the color naming alone. Sutrop points to a color term *emerald* which might be either green or blue for the speakers of the same native language [14]. Moreover, Estonian *sinakasroheline* “bluish-green” and *rohekassinine* “greenish-blue” can

actually refer to the same color in the color space, despite of belonging to the “blues” or to the “greens.” Speakers of different dialectal varieties of the same language can also tend to speak differently about colors [11]. This claim supports the fact that everyday communication is based on the frequent occurrence of specific color terms that are applied for some daily concepts which might not be present in another culture or community (e.g., the colors of national flags, specific food or beverages, fruits or greenery, etc.).

Translation of Colors in Figurative Language

As language is often viewed in relation to cognitive processes and their speakers, the translation of color language has been studied both in literal language (as taken into account beforehand) and in figurative language. Figurative language refers to idioms, metaphors, metonyms, or larger units of text, such as phrases, and is also used in humor and puns. Often it is difficult to make a difference between diverse types of figurative language, sometimes all these types are referred to as color metaphors or color idioms.

One characteristic of color terms in figurative language is that color terms are no longer designating a perceptual hue, e.g., “red” in expression “he was caught red-handed” where “red-handed” does not refer to red hue per se [13]. Not all color terms participate in figurative expressions in the same proportion and some color terms are even

rare to be found in such expressions, e.g., color term *orange*, while other color terms are used in figurative expressions in large proportions, e.g., *black*, *white*, and *red*, despite the language. However, different languages possess different color metaphors and translating them from source language into target language might cause translation dilemmas and one should always rely on the context of color terms used figuratively.

Four types of translation strategies can be discerned in translation of figurative color expressions [20]. First, reproducing the color metaphor with a coequal color metaphor in the target language (e.g., *rose-colored glasses* remains *rose-colored glasses* in a target language); second, replacing the color metaphor without a color word, but preserving a metaphorical expression in the target language (e.g., English color metaphor *blue in the face* could be translated into various target languages using other color words (e.g., *green*, *red*) or replacing a color word with random metaphorical expression); third, converting the color metaphor to a paraphrase (e.g., English metaphors *purple prose* or *yellow-bellied person* seem to be language specific and often need to be paraphrased into other languages); and fourth, omitting the color metaphor if it is redundant or untranslatable. Each language has color metaphors that are shared by different languages and widely understood in diverse cultures, but there are also language- and culture-specific metaphors which do not have equal counterparts in other languages and cultures. It seems that the more novel the metaphor, the less it is shared widely between different languages and cultures. In any case, metaphor translation should always be carried out meticulously, taking into account many linguistic and cultural factors.

Synonyms

Translucency

Definition

Transparency/translucency: (a) the degree of visibility of an object through a medium; (b) the property of a material or substance by which objects may be seen through that material or substance. Transparency occurs when objects are clearly perceived through the medium, while translucency occurs when they appear hazy. Very often the term transparency is used instead of translucency.

General

The episcotister-based model is suitable to describe the perception of transparency as it

involves different areas separated by clear margins, while variations of this model are required to deal with translucency due to blurred edges which add some degree of opacity to the impression of transparency [1].

First, figural and topological conditions, not discussed here, must be met: they essentially consist of figural unity of the transparent layer, continuity of the boundary line, and adequate stratification. Another important factor which strengthens the figural organization is movement, either of the background or of the transparent medium; this in turn makes transparency more evident. Transparency can also disambiguate objects (plaids) moving in different directions which otherwise would appear as a structure moving in another direction. Devices which induce strong depth perception, like natural or simulated stereopsis, also increase the appearance of transparency.

Transparency involves the distinct perception of two different colors, that of the background in the rear and that of the transparent layer in front where they are superimposed.

This part of the definition is very restrictive as there are cases in which one sees objects behind and through another object, but the colors perceived in the overlapping area amazingly differ from those in plain view. In these cases, no color constancy is achieved, and no model seems presently applicable.

History of the Model

Models are mathematical interpretations of physical phenomena, with characteristics analogous to those to be described, whose explanatory structure is heuristically applied to not yet fully understood phenomena (for instance, the atomic planetary model by Rutherford, the hydraulic analogy of electricity, and so on). A different definition of models includes just the mathematical formulation of relevant relationships which describe the phenomenon.

The episcotister model of transparency derives from experiences based on rotating wheels, used to produce different colors by mixing two or more

sources of radiation. Most times the disk is divided into two or more differently painted parts. The disk is rotated at a fusion speed where the human visual system cannot distinguish the different parts and generates the perception of only one color. This method of mixing radiation was made famous by Maxwell from whom it took the name. Sometimes, instead of a solid disk, only two symmetrical sectors are spun in order to mix rays from the background with those from the solid sectors. Although the laws governing these kinds of mixtures are well known, the actual perception does not always conform with the prediction of seeing one resulting color, as sometimes two colors are seen in the overlapping area. This outcome happens when some figural conditions are fulfilled and the figure of a transparent disk is visible in front of a background completely or partially covered and stratified in depth. This experience led to theoretical and experimental analysis of the psychological impression of transparency.

Field of Applications

The concept of transparency has been applied to food and drink analysis, skin and cosmetics, medicine, dentistry, architecture, textile manufacturing, art, graphics, design, fashion, painting, printing, and others.

Overview

Metelli's Episcotister Model of Perceptual Transparency

Metelli's model [2] consists of a wheel, rotating at fusion speed in front of a background, divided into two parts: an empty sector (totally transmitting area) and a solid sector (reflecting area). It is a kind of special filter, like a riddled surface, which transmits and reflects light at the same time.

Through the open part of the episcotister (or through the holes of the riddled surface), light coming from the object behind it can reach the observer's eye without being spectrally modified. The size of the open sector (or of the holes in

the riddled surface) determines how much light is transmitted to the observer: from a maximum when the whole disk is completely open to zero when the whole disk is solid. Therefore, the episcotister and the riddled surface behave like a neutral filter by decreasing the intensity of the radiation passing through them by a certain amount without changing its spectral distribution.

In turn, the solid part of the episcotister (or the solid part of the riddled surface) reflects radiation to the observer, and this is mixed with the radiation from the back. As both the open and the filled sectors of the episcotister (or the holes and the solid part of the riddled surface) together cannot be larger or smaller than the whole disk (or surface), their proportion can vary from 0 to 1: if α is the proportion of the open sector to the whole disk, $(1-\alpha)$ is the proportion of the solid sector (or of the solid riddled surface). As one increases, the other decreases accordingly: for this reason, the mixture of the two lights, that coming from the background and that coming from the surface of the episcotister (or riddled surface), is a special kind of mixture called partitive. If b is the vector describing the radiation coming from the background not modified by a filter and t is the vector describing the radiation coming from the solid surface of the filled episcotister, the presence in the rotating disk of an open sector of size α determines the partitive mixture described by the following equation:

$$q = \alpha \times b + (1 - \alpha) \times t \quad (1)$$

where q is the vector describing the mixture of the two radiations (b and t) arriving at the observer's eye.

This equation perceptually means that the back color b is visible in the color q proportionally to α and the color corresponding to t is visible in q proportionally to $(1-\alpha)$. The reduced visibility of the two colors due to the transparency factor means that they are not perceived as completely in plain sight, but one appears transparent and the other seen by transparency. Both, the radiation coming from the back opaque objects and the front transparent object, arrive at the observer reduced in intensity but unchanged in their

spectral composition. Therefore α indicates how much color of the background is visible in the overlapping area: this dimension corresponds to the degree of perceived transparency of the front object and, according to Metelli, is a logarithmic function of it, while α is a neutral (achromatic) multiplicative factor. The additive factor t , which can be interpreted as either the reflectance characteristic of the object or the light (luminance) reflected from it, corresponds to the color of the filter and can assume any value from 0 to 1 (black and white, respectively).

If the episcotister rotates over a uniform background, it appears like an opaque disk, and the same happens when physically transparent sheets are superimposed over a uniform surface. This effect shows that physical transparency is not a sufficient condition to perceive transparency. Another, particular, case of transparency is obtained when a transparent sheet completely covers a background figure without sharing its' margins: this effect has been little studied [3]. The case of riddled surfaces can be extended, by analogy, to textured surfaces, in which the density of the texture plays the role of color.

Equation 1 can be interpreted in two different ways, by analogy with a chemical reaction: when reading it from right to left, it means that the partitive mixture of the two colors b and t gives rise to the resulting and univocally defined color q ; but if one reads it from left to right, the equation can describe a color scission, that is, the color q can partitively split into the two components b and t . This scission, described by many researchers, would be in the model the opposite process of fusion and occurs in the perception of two colors in the same area, one in front and the other in the back. In different words, this scission would be a case of double representation in Gestalt terms. In this latter case, however, an indefinite number of b and t pairs can be obtained because α is not determined. Therefore, at least two equations are necessary to derive a specific pair of b and t , and a second background color seen through the transparent object must be present. For instance, in Fig. 1, the episcotister should not only rotate over the green background figure but also over the white background a , and in this case another partitive mixture would be described by the following equation:

Transparency,

Fig. 1 Top row: three different episcotisters over three identical backgrounds. b = vector defining the color of the background; t = vector defining the color of the solid sector of the episcotister; q = vector defining the color of the overlapping area; α = a measure of the open sector of the episcotister, which can vary from 0 to 1. Middle row: three riddled circular surfaces. The holes/total surface ratio (α) can vary from 0 to 1. Bottom row: the perceptual effects

$$p = \alpha \times a + (1 - \alpha) \times t \quad (2)$$

where p is the vector describing the mixture of the two radiations (a and t) arriving at the observer's eye.

The determination of α and t , characteristics not present in the stimulation, can be univocally found, starting from the colors of the display in the bottom row of Fig. 1 according to the following equations:

$$\alpha = (p - q)/(a - b) \quad (3)$$

$$t = ((aq) - (bp))/(a + q - p - b) \quad (4)$$

Once the a (the lightest area which is perceived in the background) and b background colors and t , the color of the transparent virtual object, have been chosen and the degree α of transparency is selected, the regions of the mosaic of Fig. 2 are filled with the colors determined according to Eqs. 1 and 2.

The colors of the transparent disks and their degree of transparency can be computed according to Eqs. 3 and 4 from the colors of Fig. 2. The formal independence of α and t is a feature of the model. The square wave margins between colors in the overlapping areas are characteristics of the transparency effect, while blurred margins denote translucency [3, 4]. The

alpha blending procedure in computer graphics is based on this model [5].

The model of the episcotister applied to transparency phenomena entrains also some constraints and consequences. The most important is that α [5] cannot be higher than 1 or smaller than 0 (an open sector beyond 360° or below 0° is inconceivable). Thus, by assuming a is the vector of the lightest color in the background and b the other background color (both perceived as such), the difference $p - q$ must be smaller than the difference $a - b$: the contrast (here measured as a color difference) between the colors covered by the transparent object is always lower than the contrast between the two background colors in plain view. In other words, the transparent object reduces the color contrast in the overlapping area. Secondly, as α must be positive (a negative open sector is a nonsense), the color difference between p and q must go in the same direction of the color difference between a and b . If these conditions are not met, usually transparency cannot be perceived, and the model cannot be applied, i.e., nothing can be stated about the possible transparency effect on this basis.

Transparency and Color Constancy

Transparency, like illumination, involves color constancy: first, the colors of the background perceived through the transparent medium should appear the same as those in plain view, and secondly, the color of the transparent medium should also appear the same in all its parts. The analogy with illumination is justified by the often quoted example of a transparent medium as a spectrally selective filter. Models based on simple filters have been shown not to work because the colors of the overlapping regions can be quite unexpected and sometimes color constancy does not hold at all: for instance, through a suitable red filter, a red surface may appear white and a green surface may appear black. Therefore, filter models usually include either the need of previous experience or some constancy constraints. A model based on the illumination analogy [6] considers the cone excitations as the basis for describing the

Transparency, Fig. 2 Transparent gray disks of different t color (at left) and different degrees (α) of transparency (at right) over a white and black chessboard

Transparency, Fig. 3 An example of impression of transparency without color constancy. (From Metzger [8]). When the disks are rotating, the impression is much stronger

necessary color conditions of an impression of transparency. This can occur when cone-excitation ratios between the colors in plain view ($a, b, \dots$) remain the same between the colors ($p, q, \dots$), i.e., under the transparent medium. Although color constancy is a strong requirement for perceiving transparency, it can be very weak or even null, but nevertheless a generic impression of transparency is still possible (Fig. 3). This makes the study of perceptual transparency quite difficult [7].

Transparency and Contrast

The model specifies a, b, t, p , and q by the achromatic reflectance characteristics of the surfaces (objects, materials, media) and describes the reduced contrast in the superimposition area by a reflectance difference, while further developments of the model specify colors by lightness Munsell values [9], by luminance [10], or by log luminance [11]. On the other side, there is no uniquely shared measure of contrast, and sometimes one can use the Michelson contrast [4] which seems to supply a better fitting model, suitable to explain why usually light filters seem more opaque and dark filters more transparent, although this model too is not generally applicable [12]. In any case, the filter reduces the contrast of the colors seen behind it because as they get closer, the filter gets denser (or less transparent)

[5]. Apparent contrast is further reduced by blurred edges [3].

Color contrast is relevant in determining the relative stratification of the surfaces, i.e., what is seen in front and behind, as higher contrast results in larger distances in depth. Contrast does not depend only on color difference but also on the shape of the margins: the Craik-O'Brien-Cornsweet edges (blurred versus sharpened) can invert the contrast appearance and as a consequence the relative depth of the surfaces, making transparent what was opaque and the reverse [13]. This effect can be obtained also by simple line drawings, where their contrast with the background determines the different object stratifications and the consequent transparent appearance.

A Qualitative Account of the Model in the Achromatic Domain

The possibility of perceiving transparency can be described as a function of the ordinal position of colors in the regions divided by X junctions [14, 15, 16]. If all colors present in a transparent display are achromatic, and therefore characterized by one dimension, two ordinal conditions of transparency are prescribed by the model:

$$|a - b| > |p - q| \text{ and } p > q \text{ if } a > b \text{ (or } p < q \text{ if } a < b).$$

A better prediction of transparency is achieved with the single ordinal condition: $p \in (a, q)$ or $q \in (p, b)$ [16].

Another improvement of the model states that, instead of Eq. 3, the apparent density ψ (inverse of transparency) of the filter [17] depends on three color differences:

$$\psi = w_1 |a - p| + w_2 |b - q| + (1 - w_1 - w_2)(k - |p - q|) \quad (5)$$

where the weight coefficients w_1 and w_2 express a compromise between the three differences.

Transparency, Fig. 4 Attilio Taverna. Left: *Sentieri interrotti* 1992. Right: *Blue geometric storm* 1992. Transparency effects are obtained by painting each overlapping

area with the partitive mixture of the back and front colors. Also perceptual space organization is affected by transparency

Transparency and Pictorial Art

Since centuries, the transparency effect is used both to represent translucent or transparent objects and to enrich the color variety of a painting.

Many methods have been adopted to render transparent objects, all having in common the purpose of showing two colors, one in front and one in the back, the latter visible through the former. One method is just to put in the overlapping areas the color which would be obtained by partitive mixture of the back and the front colors (Fig. 4), following, not necessarily consciously, the episcotister model.

Another method reaches the same results by using small mosaic tesserae to be viewed at a certain distance in order to produce spatial color mixtures (Fig. 5).

Another method is the veiling procedure obtained by using semitransparent paints, as shown in Fig. 6: the back and the transparent colors are both visible where they overlap. Lastly, a final method consists of accentuating the borders between the opaque and the transparent medium, by simulating Cornsweet edges and introducing a depth displacement between opaque and transparent surfaces.

Improvements of the Model

As the colors in plain view and those in the overlapping areas, represented in a suitable color system, according to the model converge in a point corresponding to the color t , the model has been called convergence model [5]. The convergence point can lie outside the color solid, and perception of transparency can still be possible [7], although not always [18]. In this partitive model, α defines the position of the color p between the color a and the color t , and colors necessarily have to be expressed in colorimetric quantities. There are different methods, used in different theoretical models, to compute α from the colors of the image, but the result is always a value of physical nature whose relationship with the corresponding perception of transparency is not linear.

From a different point of view, the same mathematical *model* can be used without physical implications, and in this case α is a distance measure in a perceptual space. While in Metelli's model α has no direct perceptual meaning, except that of the order (more or less transparent), values of α with perceptual meaning can be derived according to traditional methods by logarithmic transformations [12]; for achromatic colors, α can also be computed by using Munsell values instead

Transparency, Fig. 5 Ravenna: Baptistery of Aryans, fifth century (detail). Picture by Incola (Wiki) (http://it.wikipedia.org/wiki/File:Soffitto_Battistero_Ariani_Ravenna.jpg#filehistory). Water and body colors seen from

some distance partitively fuse because under spatial discrimination threshold, an impression of transparency arises in the observer

Transparency, Fig. 6 Hans Memling, fifteenth century. Portrait of a young lady (Sibylla Sambetha). Musea Brugge, Sint-Janshospitaal. (Copy purchased from Lukas Art in Flanders, o.n. 1376 (2012))

of reflectance or luminance [19], since in the Munsell system equal color differences are represented by equal perceived distances. Colorimetric color difference systems (for instance OSA_UCS, CIELUV, CIELAB, CIECAM, and so on) can be used to compute a perceptual α , of course with varying scales. This latter way of computing α produces results with better perceptual agreement than the former [19], and many software programs implement it. The reason is that the color relationships entering the computations have a perceptual basis (percept-percept coupling [20]), not a physical or physiological one. The step of using perceptual measures of colors describes a radical change compared to the traditional psychophysical procedures, and rightfully it can be considered belonging to the phenomenology of colors, science inside the world of appearance. Unfortunately, the number of not well-fitting results is still unsatisfactory. A further step has been accomplished. According to current opinion, the perceived distance between the two colors a and t should not be large; otherwise transparency perception would not occur. The reason is that the color p should not be just a

Transparency, Fig. 7 In the upper part, the external areas represent, in isolation, the background in plain view and the internal areas the overlapping surfaces, whose colors have been defined in terms of the NCS. The bottom part shows the complete mosaic resulting when the separated areas are joined

colorimetric intermediate between a and t but should appear *similar* both to a and t [21]. This would be a strong condition to see both colors in the overlapping area. Large differences between a and t would not result in perceived transparency because there is no color resembling both at the same time. In these cases spatial induction can sometimes add the necessary missing shades (especially if p is a neutral color). A model has been proposed [21] in which the Natural Color System [22], based on the perceptive *similarity* of any test color to the six Hering prototypical unique colors W K Y R B G, is used to describe the relevant color relationships in transparency perception (Fig. 7).

The naming of colors in this system clearly shows similarity relationships and therefore the possibility of seeing two colors in a not-unique (i.e., perceptually mixed) color. The limits of the models are limits in color vision: no color can resembles two opponent colors at the same time in the same place, and therefore they cannot be seen in the overlapping area of a transparent object. On the other side, it is known that a weak form of transparency is possible in which the colors of the background are not clearly visible

in the overlapping areas and the transparent object does not show a uniform color [8].

Definition

Tritanopia (from the Greek *tritos*: third + *an*: not + *opia*: a visual condition) is a congenital form of severe color deficiency (dichromacy) affecting the blue-yellow opponent color system. Tritanopes do not distinguish between colors along a specific direction in color space (tritanopic confusion lines) and are able to match all colors using two primaries (unlike trichromats who require three primaries). Tritanopia follows a dominant pedigree pattern and is linked to chromosome 7, where damage to the gene encoding the photopigment opsin results in the absence of functioning S-cones, cone cells containing the short-wavelength (S-) photopigment. Tritanopia is rare, not sex-linked, with great uncertainty as to its incidence, although some estimates place this at 1 in 13,000 or fewer in the Caucasian population. The condition can be partial rather than complete, i.e., tritanopia lies at the extreme of a continuum of tritanomaly in which some capacity remains to discriminate colors along confusion lines.

Retinal Mosaic

At the retinal level, tritanopia is an absence of functional S-cones (► [CIE Physiologically Based Color Matching Functions and Chromaticity Diagrams](#)), i.e., cone cells expressing a photopigment containing an S-opsin component, tuned for selective sensitivity to the short wavelengths of light (blue) [1, 2]. These cones comprise only about 8% of the retinal mosaic. Even in normal trichromats, they are absent from the central region of the fovea, resulting in “foveal tritanopia” affecting the perception of sufficiently small stimuli when they are fixated [3, 4].

Congenital Tritanopia: Genetic Background

Functional loss of the S-cone photoreceptor cells is caused by point mutation in the gene on chromosome 7 that codes for the S-opsin component of the cone photopigment (sensitive to shorter wavelengths) (► [Genetics of Photoreceptors, Genetics and Color Vision Deficiencies, Genes of Cone Photopigments, Genes and Cones](#)). The resulting amino acid substitution may prevent the S-opsin from functioning, or it may fold into an aberrant conformation blocking it from being transported to the ciliary segment of S-cone cells [1, 5].

The condition follows a dominant pattern of inheritance: S-cones must contain two undamaged copies of the gene to function properly [6, 7]. However, pedigrees often display variations in penetrance with incomplete tritanopia in some family members who retain some blue-yellow discrimination.

Variation in phenotype may also indicate that loss of S-cones is progressive, and incomplete, in some family members. This is supported by retinal imaging showing S-cone degeneration subsequent to formation of the retina [8].

Disease processes and exposure to environmental toxins can lead to the same end point, i.e., acquired tritanopia (► [Color Perception and Environmentally Based Impairments](#)). In

particular, the phototoxicity of prolonged exposure to intense short-wavelength light can cause S-cones to degenerate. In other forms of acquired tritanopia, the damage is localized elsewhere in the processing of the S_0 signal, such as the ganglion cells or the optic nerve [9].

Confusion Lines

Tritanopic color processing lacks the $S-(L+M)$ or S_0 signal, produced by bistratified retinal ganglion cells comparing the S-cone signal and the combined L- and M-signals (Color Vision, Opponent Theory); hence, there is no difference in appearance among colors which differ only in how much they stimulate S-cones. Examples of colors confused by tritanopes are blue and green or violet, gray, and yellow. Plotted in a chromaticity diagram (► [CIE Chromaticity Diagrams, CIE Purity, CIE Dominant Wavelength](#)), the confused colors lie on straight “confusion lines” that converge at the tritanope copunctal point (Fig. 1).

A related phenomenon is observed in edge perception, where the border between two regions of equiluminant color dissolves if the colors lie on a tritanopic confusion line (e.g., yellow and gray or green and blue). The perception of border distinctness is tritanopic, with no contribution from the S_0 signal, as a consequence of the sparseness of S-cones and chromatic aberration of the lens [10].

Wavelength Discrimination

Because S-cones are insensitive to mid- and long-wavelength lights, tritanopic hue discrimination, as a function of wavelength λ , is similar to the normal trichromat function for $\lambda > \text{ca. } 530 \text{ nm}$, with the discrimination threshold $\Delta\lambda$ reaching a minimum at about 570–580 nm near the tritanopic “neutral point” (see below). Tritanopic discrimination deteriorates for blue-green hues where the L- and M-cones are equally sensitive, with $\Delta\lambda$ peaking at ca. 470 nm and then improving at shorter wavelengths [11].

Tritanopia, Fig. 1

Confusion lines indicate colors that cannot be distinguished by a tritanope. The line going through the white point indicates neutral (achromatic) colors. The lines converge at the copunctal point defining the chromaticity of the missing S-cone fundamental. Drawn in the CIE 1931 chromaticity diagram. (Source: Benjamin, W.J. (ed.), *Borish's Clinical Refraction* (1998), Fig. 20) (Elsevier Books, Copyright Clearance Center: Licensee: David Bimler; License Number: 3532171403672)

**Luminous Efficiency**

S-cones normally contribute little or nothing to perceived luminance, but S-cone signals can make a contribution under certain conditions of adaptation and temporal flicker. Specifically, with intense long-wavelength background, S-cone stimulation exerts a negative but phase-delayed influence on luminance, as if inhibiting the combined L-and M-cone signal [12, 13].

Color Perception

A tritanope recognizes far fewer distinct colors than a trichomat (► [Color Categorization and Naming in Inherited Color Vision Deficiencies](#)). When naming spectral colors, tritanopes experience one “neutral zone” of subjective gray for light with midpoint at λ ca. 570 nm (yellow) and another for short-wavelength violets, at about $\lambda = 410\text{--}420$ nm [14]. For a tritanope, all equiluminant colors, instead of being arranged in a two-dimensional plane (► [Psychological Color Space and Color Terms](#)), form a single-

dimensional line, running from “cool” to “warm” colors between the two extremes of saturated green and saturated red. This single dimension combines the usually separate chromatic qualities of “saturation” and “hue.” Tritanopes distinguish approximately 44 steps along this line, each corresponding to a separate band of interchangeable colors [1]. This tritanopic linear representation of equiluminant colors is part of a broader reduction of a three-dimensional into a two-dimensional color space.

The subjective qualities of tritanopic experience remain unclear. Tritanopes do use the words “blue” and “yellow” when describing lights and surface colors [4, 11]. Dichromacy simulation software, which converts color scenes to show how a tritanope would see these, uses the convention of a red-green scale [15].

Diagnosis of Tritanopia

Acquired blue-yellow deficits can be symptomatic of illness or chemical exposure (► [Color Perception and Environmentally Based Impairments](#)). Thus,

standard tests of color abnormality, although targeted primarily at congenital red-green deficiency, do not ignore tritanopia completely. Pseudoisochromatic plates ([► Pseudoisochromatic Plates](#)) and arrangement/panel tests directly address a tritanope's perceived similarity of colors along the confusion axis.

The Hardy-Rand-Rittler test ([► Color Vision Testing](#)) contains pseudoisochromatic diagnostic plates to detect tritanopia and gauge its severity, while the Farnsworth F2 plate is designed specifically for that purpose (The widely used Ishihara series contain no plates targeting tritanopia). Each pattern presented in these plates is defined by a color difference that disappears for tritanopes, so that the design vanishes or is supplanted by an alternative design, demarcated by a different chromatic distinction.

In the arrangement tests (Farnsworth-Munsell 100-Hue test, Farnsworth D-15 test), the one-dimensionality of a tritanope's color "plane" collapses a color circle ([► Color Circle](#)) into a line, causing drastic departures from a normal observer's sequence. Errors, or cap transpositions "distances," are summed to quantify the severity of tritanopia. Plotted graphically, the transpositions in the D-15 manifest as diametrical circle crossings, indicating the tritanopic angle of the confusion axis ([► Color Perception and Environmentally Based Impairments](#)).

The "gold standard" of diagnosis of tritanopia is the Moreland equation, with stimuli presented in a small viewing field (2°) in the Moreland anomaloscope [16], in which a cyan standard (480 nm with a small admixture of 580 nm) is matched by mixing indigo (436 nm) and green lights (490 nm). Decreasing discrimination along the tritanopic confusion lines increases the range of acceptable mixtures. Notably, when field size is increased beyond 1°, residual blue-yellow discrimination can be detected in some cases; at 8° only complete tritanopes accept the full range of color mixtures as a match to the cyan standard [7].

More recently developed computerized tests for color vision diagnosis, the Cambridge Colour

Test and the Colour Assessment and Diagnosis test ([► Color Vision Testing](#)), interactively quantify any loss of chromatic sensitivity along the tritanopic confusion line. For a tritanope, in the frame of the CIE (u'/v') 1976 chromaticity diagram ([► CIE \$u'\$, \$v'\$ Uniform Chromaticity Scale Diagram and CIELUV Color Space](#)), a MacAdam ellipse of indistinguishable colors displays a major axis lengthened to infinity and orientation pointing to the tritanope copunctal point.

Tubular and Compact Fluorescent Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
Netherlands

Synonyms

Low-pressure mercury gas discharge lamps

Definition

A lamp that produces light as a result of an electrical discharge, generated between two electrodes, in a low-pressure mercury vapor that is contained in a transparent tube whose inside is coated with fluorescent powder that converts the ultraviolet part of the emitted radiation from the discharge in visible light.

Types of Tubular Fluorescent Lamps

Fluorescent lamps belong to the family of low-pressure mercury gas discharge lamps. They are by far the most widespread discharge lamp types. They are available in both tubular and compact versions. Although the operating principle of compact fluorescent lamps is largely the same as that of the tubular version, their construction and performance are in many ways different from that of the tubular version [2, 3].

Working Principle

The discharge tube of a fluorescent lamp is filled with an inert gas and a little mercury and has an electrode sealed into each end (Fig. 1). To facilitate starting, the electrodes of most fluorescent lamps are preheated prior to ignition, which is accomplished by means of a high-voltage pulse, generated by an external device called the igniter or starter. (Igniters are available as simple glow-switch starters or as electronic devices.) When the lamp is switched on, the electrodes begin emitting electrons, and through the collision of these electrons with the gas atoms, the ionization process starts. The inert gas is then heated up, and the mercury inside the lamp is completely evaporated to give a mercury vapor pressure of about 0.8 Pa ($8 \cdot 10^{-6}$ atm). The emitted electrons collide with and excite the mercury atoms, resulting in the emission of ultraviolet radiation and a small amount of blue visible light. The inside of the discharge tube is coated with a mixture of fluorescent powders. The ultraviolet radiation is

Tubular and Compact Fluorescent Lamp,

Fig. 1 Main parts and principle of operation of a tubular fluorescent gas discharge lamp (TL) [1]

converted to visible light when it passes through the fluorescent powder coating.

Like almost all gas discharge lamps, a fluorescent lamp cannot be operated without some device to limit the current flowing through it. This device, usually in the form of an inductive coil, is called a ballast. Fluorescent lamps also need, again like most discharge lamps, an igniter for starting the lamp.

Tubular Fluorescent Lamps

Tubular fluorescent lamps are widely used in offices, schools, shops, and low-ceilinged industrial premises. So today their use is mainly indoors.

Materials and Construction

The main parts of a tubular fluorescent lamp are (see Fig. 1):

- Glass tube
- Fill gas
- Electrodes
- Fluorescent powder

Glass Tube

The tube of a normal fluorescent lamp is made of glass that is doped with a special material that blocks that UV radiation from the mercury discharge that is not converted by the fluorescent powder into visible light.

The original fluorescent lamp had a diameter of 38 mm. This tube diameter is usually characterized as T12, where the 12 stands for 12 times one-eighth of an inch (Table 1). This type of fluorescent tube is seldom seen today. During the late 1980s, a smaller and more efficient version was introduced that has a diameter of 26 mm. Today an even thinner and more efficient version has become the standard: the TL5 with a diameter of 16 mm. Even thinner fluorescent lamps are produced, but these are not for use in general lighting.

Fill Gas

The gas filling in a fluorescent lamp consists of a mixture of mercury vapor and an inert gas. The inert gas has three functions:

- To facilitate ignition, especially at lower temperatures
- To control the speed of the free electrons
- To prolong the life of the electrodes by reducing evaporation of electrode material

The inert gas usually consists of a mixture of argon and neon, although sometimes krypton is used as well.

Electrodes

The function of the electrodes is to provide free-running electrons, which are necessary to start and maintain the discharge. A fluorescent lamp electrode consists basically of a tungsten filament (Fig. 2) that is coated with the so-called emitter material to facilitate electron emission.

Tubular and Compact Fluorescent Lamp,

Table 1 Fluorescent lamps with different tube diameters and their designations

Tube type	Diameter (inch)	Diameter (mm)
T12	12 * 1/8	38
T8	8 * 1/8	26
T5	5 * 1/8	16
T2	2 * 1/8	6
T1	1 * 1/8	2.8

Tubular and Compact Fluorescent Lamp, Fig. 2 Triple-coiled filament electrode [1]

Fluorescent Powder

The small crystals of the fluorescent powder applied to the inside of the discharge tube absorb the UV mercury radiation and convert it into visible light (this physical phenomenon is called luminescence). Different fluorescent powders convert the ultraviolet radiation into visible light of different wavelengths and thus different colors (Fig. 3).

By mixing different fluorescent powders in different proportions, lamps producing different tints of white light can be made. The type and composition of the fluorescent powder is the most important factor determining the light characteristics of a fluorescent lamp, such as color temperature, color-rendering index (R_a), and, to a large extent, the luminous efficacy of the lamp (lm/W). Some fluorescent powders convert the ultraviolet radiation into wavelengths covering almost the whole visible spectrum. Such powders, therefore, produce white light when used alone. However, their color rendering and efficacy are poor ($R_a < 70$ and lm/W < 80). Because these powders

lose some of their conversion activity relatively quickly, lamp-lumen depreciation is relatively large. Nowadays these lamps are hardly ever produced. Today fluorescent lamps often employ a mixture of three fluorescent powders, each having a very narrow spectrum band in red, green, and blue. In this way, white light is again obtained but of better color rendering and efficacy ($R_a > 80$, lm/W up to 105). The lamp-lumen depreciation with these powders is very low ($< 10\%$). For cases where extremely good color rendering is required, a mixture of more than three powders is used, resulting in lamps with excellent color rendering ($R_a > 90$), very low lumen depreciation, and high luminous efficacy (slightly smaller than the previous version, viz., up to some 90 lm/W).

Properties

Energy Balance

Just below 30% of the input power is converted into visible radiation and a very small part into UV radiation. The rest is lost in the form of heat (at the electrodes, in the discharge itself, and as infrared radiation). Compare the figure of 30% with 8 and 12% for incandescent and halogen lamps, respectively.

System Luminous Efficacy

As with most lamps, the luminous efficacy of tubular fluorescent lamps is dependent on the wattage of the lamp and the color quality of the light it gives. Types with color rendering better than R_a 80 and with low lumen packages have a system luminous efficacy starting at 50 lm/W, while lamps with higher lumen packages reach efficacies up to some 105 lm/W. Lamps with

Tubular and Compact Fluorescent Lamp, Fig. 3 Different types of fluorescent powder. *Left*, under white light, and *right*, the same fluorescent powders under UV radiation [1]

Tubular and Compact Fluorescent Lamp, Fig. 4 Spectral energy distribution of a fluorescent lamp color type 827: T_k 2700 K and R_a 80 [1]

extremely good color rendering ($R_a > 90$) have 15% lower efficacies.

Lumen-Package Range

Common tubular fluorescent lamps are produced in the range from some 500 to 6000 lm (corresponding wattage range approximately 8–80 W). Special very-high-output lamps are also produced in versions up to some 9000 lm (120 W).

Color Characteristics

As has been mentioned, by mixing different fluorescent powders in different proportions, lamps with different spectra can be produced. As with all gas discharge lamps, the spectrum is discontinuous. Figures 4, 5, and 6 show the spectra of fluorescent lamps with different color temperatures T_k and color-rendering index R_a .

The color type designation used for fluorescent lamps is standardized, with the first digit standing for the color-rendering index R_a and the last two digits for the color temperature T_k . Thus, the color type 840 stands for a color-rendering index value R_a in the 80 ties and a color temperature of around 4000 K.

Present-day quality fluorescent lamps are produced in a whole range of color temperatures varying from 2700 K (warm white or incandescent lamp color tint) to 6000 K (bluish white), most of them in two color-rendering qualities with R_a in the 80 ties (800 series) and 90 ties (900 series), respectively. For special applications, versions are produced with extremely high color temperatures (up to some 17,000 K) with color rendering in the 80 ties. Today, fewer and fewer of those fluorescent lamps with poor color-rendering qualities (viz., R_a around 65 or less) that were produced in the past are produced.

Lamp Life

During the operation of a lamp, the electrodes lose emitter material due to evaporation and as a result of the bombardment with ions from the discharge. This is the main cause of lamp failure: the lamp will no longer start, due to a broken electrode, or else it flickers because insufficient emitter material remains. The lifetime of fluorescent lamps and gas discharge lamps, in general, is thus very much dependent on the construction and materials of the electrodes. Conditions that influence lifetime are principally the type of gear used, the switching frequency, and the ambient temperature. The switching frequency plays a role because the high-voltage peak needed for ignition causes the electrodes to lose some of their material (sputtering). The more accurately the igniter-ballast combination preheats the electrodes, the less severe this effect is. The occurrence of such things as shocks or vibrations, different burning positions, and supply-power variations can play an additional role.

Today's high-quality fluorescent tubes have economic lifetimes (based on 20% mortality) of 15,000 h to more than 20,000 h if used on a so-called high-frequency or HF ballast and around 12,000 h when used on an electromagnetic ballast. For situations where the actions needed to replace lamps are expensive, special, and more expensive, long-life fluorescent lamp versions are available with lifetimes ranging from some 40,000 to 65,000 h. This long life is obtained by means of a special electrode design and construction.

Lamp-Lumen Depreciation

The main cause of lamp-lumen depreciation in a fluorescent lamp is that the fluorescent powder slowly becomes less active as a result of chemical attack by mercury ions. There may also be some blackening of the tube wall from the electrodes. For cool-white and cool-daylight lamp types, the lumen depreciation is higher than for lamps with a warmer tint. This is because of the faster depreciation of the blue fluorescent powders. Lamp-lumen depreciation for present-day high-quality

fluorescent tubes is around 10% after some 20,000 h.

Run-Up and Reignition

Fluorescent lamps operated on present-day electronic control gear start very quickly (within 1.5 s) and without flickering. This last is in contrast to lamps used on the older, glow-switch starters. After ignition, the light output increases quickly up to its maximum in about 1 min. When a fluorescent lamp is switched off, the vapor pressure drops so quickly that reignition is instantaneous.

Switching

It has already been mentioned that the switching frequency has an influence on lifetime, the influence being dependent on the type of electrical control gear used. Lamps operated with HF electronic-preheat-start ballasts show in general, little sensitivity to the switching cycle. This is because of the well-controlled starting conditions of the lamp (warm start). HF non-preheat starting leads to a relatively short lamp life under frequent-switching conditions.

Dimming

Dimming of modern fluorescent lamps on high-frequency electronic ballasts down to 3% of the nominal light-output value is easy, possible with an additional circuit that changes the operating frequency.

Ambient-Temperature Sensitivity

The luminous flux of a fluorescent lamp is determined by the mercury vapor pressure during operation. The mercury vapor pressure is in turn determined by the coldest spot in the tube, normally the tube wall, which of course is also dependent on the ambient temperature. The consequence of this is that the light output of fluorescent lamps is dependent on ambient temperature. The lumen output of fluorescent lamps is generally published for an ambient temperature of 25 °C. T12 and T8 lamps have their maximum light output at 25 °C, while the smaller diameter T5 lamps give their maximum light output at 35 °C (Fig. 7). To obtain a high- and near-constant light output over a wide temperature range, the mercury in some fluorescent lamp types is

Tubular and Compact Fluorescent Lamp,

Fig. 7 Relative light output of a T8 and a T5 fluorescent lamp in relation to the lamp's ambient temperature [1]

introduced into the tube not as a pure metal but as an amalgam. Such lamps have a lumen output that is near constant over the temperature range of 25–65 °C.

Mains-Voltage Variations

If the mains voltage varies, the power consumed by the lamp changes and with it the vapor pressure and consequently the lumen output. Given an optimized lamp/electromagnetic ballast combination, a 10% deviation in power will keep the lumen-output decrease usually at less than 10%. On high-quality, high-frequency electronic ballasts, a 10% deviation in power can keep the lumen-output decrease at less than 3%. In all cases, with higher mains-voltage decreases, the lumen output decreases rapidly.

Product Range

Tubular fluorescent lamps are being produced in a wide variety of types with different properties. The more important lamp types are listed in Table 2.

Up until 1990, fluorescent tubes were operated on electromagnetic ballasts. Even today, this way of operating a fluorescent tube is called “conventional,” although operation on high-frequency or HF electronic ballasts has since become the standard. T5 lamps can only be operated on HF electronic gear.

T5 lamps are produced in an execution where the design is such that the maximum luminous efficacy is obtained: the high efficiency, HE, and series of lamps. Another type of execution is optimized for maximum lumen output at the cost of efficacy: the high output, HO, and series (10% higher lumen output and 10% lower efficacy). Very-high-output lamps (VHO) are produced as well.

Some tubular fluorescent lamps are given a coating on the outside of the tube. A silicone water-repellent coating is applied to prevent starting problems for types that are used under conditions of high humidity. Types intended for use in food stores can be given a special protective coating that prevents surrounding products from

Tubular and Compact Fluorescent Lamp, Table 2 Different tubular fluorescent lamp types

Lamp aspect	Range
Tube diameter	38 mm (T12)/26 mm (T8)/16 mm (T5)
Lamp circuit	Electromagnetic/HF electronic
Balance efficacy/lm output	High efficacy (HE)/high output (HO)/very-high output (VO)
Color temperature T _k	Standard range (2700–6000 K)/8000–17,000 K
Color rendering R _a	R _a > 90 (900 series)/80 < R _a < 90 (800 series)/R _a < 80
Color	Red, green, blue, etc.
Lifetime	Standard (up to 20,000 h)/very long (up to 65,000 h)
Ignition method	Standard/low-temperature ignition
Tube coating	No coating/coating (silicon, protective, or reflector)
Safety of operation	Standard/explosion safe
Tube length	Standard (450–1800 mm)/mini (150–500 mm)
Tube shape	Tubular/U-shaped/circular

contamination in the event of accidental lamp breakage. Some of these latter types have a spectrum that makes the appearance of food more appealing (especially meat). In reflector fluorescent lamps, a diffusely reflective coating is applied between the upper part of the inner tube wall and the fluorescent powder. The light is concentrated through the uncoated area (or “window”) of the lamp so increasing the downward component of the light (Fig. 8).

Compact Fluorescent Lamps

Compact fluorescent lamps (CFLs) were initially developed (beginning of the 1980s) for use in those applications where incandescent lamps were traditionally used. Today, the application of compact fluorescent lamps has been widened and includes not only domestic lighting but office and road lighting (residential streets) as well. For the more compact versions, alternatives in the form of solid-state lamps are becoming increasingly more available.

Tubular and Compact Fluorescent Lamp,

Fig. 8 Reflector fluorescent lamp

Working Principle

The gas discharge principle employed in compact fluorescent lamps is exactly the same as that in tubular gas discharge lamps (see previous section). Their compactness is achieved by reducing their length. This is done either by folding a longer tube into a shorter one or by joining together two or more parallel tubes so that one open pathway is obtained where free electrons and ions can move from one electrode to the other, as in a normal straight fluorescent tube (Fig. 9). The folding can be repeated, or the interconnection can be done with more than two parallel tubes (always keeping one open pathway) to further increase the size of the lamp.

Materials and Construction

As far as fill gas, electrodes, and fluorescent powders are concerned, compact fluorescent lamps are essentially the same as conventional tubular fluorescent lamps. Reference is therefore made to the previous section “[Tubular Fluorescent Lamps](#).”

The main difference in construction between compact and tubular fluorescent lamps lies in the tube shape and the lamp caps. But another point of difference is that in those compact lamps that need to work directly from the mains without any external electrical component, the igniter and ballast have to be integrated in the lamp itself. In this

Tubular and Compact Fluorescent Lamp, Fig. 9 Folding one tube (*left*) or connecting two separate tubes (*right*) to form a compact fluorescent lamp with one open pathway between the electrodes

case, the lamp foot is used for housing the control gear.

Tube

A great variety of tube shapes are produced. Figure 10 shows versions where tubes are interconnected. All these are examples of compact fluorescent lamps where the gear is not integrated in the lamp itself (compact fluorescent lamps non-integrated CFL-NI). Figure 11 shows a set of

Tubular and Compact Fluorescent Lamp, Fig. 10 Nonintegrated two-leg compact fluorescent lamps. From *left to right*: two pins with bridge connection, two pins with bend connection, and four pins with bridge connection

Tubular and Compact Fluorescent Lamp, Fig. 11 Triple-folded nonintegrated compact fluorescent lamps

Tubular and Compact Fluorescent Lamp, Fig. 12 Single-plane-folded nonintegrated compact fluorescent lamps

triple-folded types, while Fig. 12 shows two different folded, single-plane versions.

Figure 13 shows examples of compact lamps where the gear (HF electronic) is integrated in the lamp foot (integrated CFL-I). Since these lamps can directly replace incandescent lamps, it is also desirable that their shape and dimensions should be very close to those of normal incandescent lamps. Figure 14 shows two retrofit versions where an outer bulb with an internal diffusing coating also ensures that the light distribution is close to that of an incandescent lamp.

Lamp Cap

The compact fluorescent lamps with integrated control gear have the same lamp caps as normal incandescent lamps, viz., Edison screw type and bayonet caps.

In most nonintegrated, small, twin-tube versions, the starter is built into the lamp cap itself (integrated starter but nonintegrated ballast). All nonintegrated types are fitted with special caps. A large variety of caps and bases exist in order to ensure that only the correct type of lamp can be used in a given situation (especially defined by the type of gear used in the particular luminaire).

The lamp caps of nonintegrated compact fluorescent lamps are of the push-fit type (they fit by pushing them into the lamp holder). They are available in both square-shaped and rectangular-shaped versions. Lamp caps for lamps with an integrated starter employ two-pin connectors, while lamps for use with electronic control gear

Tubular and Compact Fluorescent Lamp, Fig. 13 Differently shaped integrated compact fluorescent lamps

Tubular and Compact Fluorescent Lamp, Fig. 14 Retrofit compact fluorescent lamps with shape, dimensions, and light distribution close to that of an incandescent lamp bulb

or dimmers have four-pin connectors (Fig. 10 right, Fig. 11 right, Fig. 12 right).

Properties

Energy Balance

Approximately 20% of the input power of compact fluorescent lamps is emitted in the form of visible radiation. A tubular fluorescent lamp emits

some 28% of visible radiation. The difference is mainly due to the fact that in compact lamps, the multitude of closely packed tube parts absorbs part of the light.

System Luminous Efficacy

The luminous efficacy of a compact fluorescent lamp is partly dependent on the wattage of the lamp and the color quality of the light emitted but more so on how and how many times the compact tube is folded. In low-wattage versions, good color-rendering versions have a system luminous efficacy starting at 45 lm/W, while higher-wattage versions reach efficacies of up to some 70 lm/W.

Lumen-Package Range

Compact fluorescent lamp with integrated control gear is produced in the range from some 250 to 2000 lm (corresponding wattage range approx. 5–35 W). Nonintegrated types are available in the range from some 250 to 6000 lm (corresponding wattage range approx. 5–80 W).

Color Characteristics

The color characteristics of compact fluorescent lamps are principally the same as those of normal fluorescent lamps. Reference on this point is therefore made to the previous section “[Tubular Fluorescent Lamps](#).” The range of different color temperatures and color-rendering indices available with compact fluorescents is in practice

somewhat limited compared to that found with the very wide range of tubular lamps.

Lamp Life

The lifetime of compact fluorescent lamps is very long compared with that of incandescent lamps, although it is usually shorter than that of tubular fluorescent lamps. Integrated versions (CFL-I) have, depending on the type, a rated average lifetime of between 8000 and more than 15,000 h. Note that the life of retrofit integrated CFLs is usually specified as rated average life (50% mortality), as is the case with incandescent lamps (which have an average life of 1000 h). Again, depending on the type, nonintegrated versions (CFL-NI) have economic lifetimes (based on 20% mortality) of 7000–20,000 h.

Lamp-Lumen Depreciation

The lamp-lumen depreciation of compact fluorescent lamps is similar to that of tubular fluorescent lamps. See previous section “[Tubular Fluorescent Lamps](#).”

Run-Up and Reignition

There are no fundamental differences here compared with normal fluorescent tubes. See previous section “[Tubular Fluorescent Lamps](#).”

Switching

There are no fundamental differences here compared with normal fluorescent tubes. See previous section “[Tubular Fluorescent Lamps](#).”

Dimming

Most integrated compact lamps are not dimmable. However, special, more expensive versions, with standard Edison or bayonet cap, are produced that can be dimmed to approximately 5% of full light output. Dimming of nonintegrated, four-pin, compact lamps is possible and is fundamentally the same as with tubular fluorescent lamps.

Ambient-Temperature Sensitivity

With each different lamp shape, the location of the coldest spot is also different, and this has consequences for the mercury pressure and therefore for the ambient-temperature sensitivity. With some shapes, the coldest spot is also influenced by the

Tubular and Compact Fluorescent Lamp, Table 3 Lamp properties versus lamp types

Lamp property	Range of lamp types
Gear integration	Integrated (I)/nonintegrated (NI)
Tube diameter	13 mm/18 mm
Shape	Various
Lamp length	80–200 mm (CFL-I)/100–600 mm (CFL-NI)
Lamp circuit	Electromagnetic/HF electronic
Color temperature T_k	Standard range (2700–6000 K)
Color rendering R_a	$R_a > 90$ (900 series)/ $80 < R_a < 90$ (900 series)

burning position of the lamp (e.g., base up or base down). The folded, integrated versions often use amalgam instead of pure mercury to stabilize the mercury pressure and thus to minimize the temperature sensitivity.

Mains-Voltage Variations

No fundamental differences compared with tubular fluorescent tubes. See previous section “[Tubular Fluorescent Lamps](#).”

Product Range

Compact fluorescent lamps are being produced in many types with different properties. The more important lamp properties for which different versions are made are gear integration (integrated or nonintegrated), tube diameter (13 mm and 18 mm), shape, tube length (related to lumen package), lamp circuit, color temperature, and color rendering. Table 3 indicates for all these lamp aspects the range of lamp types available.

Definition

When light is scattered off particles in a dusty surface or cloud, it becomes polarized. The more reflective (higher albedo) the dust particles, the lower the overall degree of polarization in the scattered light. This inverse relationship was first noted by Nikolay Umov and has accordingly become known as the “Umov effect.”

Introduction

When randomly polarized light is obliquely incident on particles in a dusty surface or layer, the scattered or reflected light becomes partially polarized to a degree that is dependent upon the viewing direction with respect to the incident light (phase angle) and, if the particles are irregularly shaped, their orientation. Since the geometry of the source-scatterer-observer light path is the same for all single-particle scattering events, this component of the light is polarized. For light scattering involving a large number of particles, the geometries are many and widely different, so that even though each scattering event might produce a net polarization, the integrated scattered light from these particles will be randomly polarized. The higher the reflectivity of the individual particles, the larger the contribution to the randomly polarized light reaching the observer from the multiple-particle scattering events. This means the higher the general reflectivity (albedo) of the

dust particles, the lower the net degree of polarization of the light reaching the observer. This relationship is described by the following inverse correlation:

$$P \propto \frac{1}{A}$$

where P is the degree of polarization and A the overall (geometric) albedo of the object. Consequently, light scattered by dim, dusty objects will be more polarized than light from bright, dusty objects.

The relationship was first described by Russian physicist Nikolay Umov in 1905 [2] and has become widely referred to as the **Umov effect** and the inverse relationship between maximum degree of polarization and geometric albedo as **Umov's Law**. It is usually described as giving a straight line with negative slope in a log-log plot of $\log(P_{\max})$ versus $\log(A)$, in a so-called linear **Umov diagram**. The degree and directional properties of the scattered light depend upon the shapes and sizes of the scattering particles and are a useful tool for investigating dusty surfaces such as the surface of the Moon or asteroids or even cosmic and interplanetary dust clouds.

One Light Ray, Scattering Off a Single Particle

Figure 1 shows a beam of randomly polarized light coming from the far background in the upper left propagating toward the lower right foreground. It is incident upon a particle, which is assumed to be “small” and “spherical,” and is scattered. The light that continues with its direction unchanged retains its initial polarization. However, in general the scattered light changes its polarization to a degree that depends on the direction in which it is scattered. Light deviated by 90 degrees with respect to the direction of the incident light becomes totally linearly polarized in a sense tangential to a circle centered on the particle and normal to the direction of the incident ray. In an arbitrary direction (the thick line in the figure), the light will be partially polarized to

Umov Effect, Fig. 1 Polarization of light by scattering off a single particle

some degree depending upon the scattering angle. If the illumination source and the observer are a large distance from the scatterers, light from a collection of particles reaching the observer after a single interaction would follow the same path geometry, and their individual polarization components would be additive and give a calculable increase in the degree of polarization seen by the observer.

In the diagram the black arrows indicate relative degrees of polarization in the horizontal and vertical directions. Totally linearly polarized light will have just one component. Unpolarized light will have its orthogonal components of equal magnitude. In general there is some degree of polarization, in which case the longer arrow indicates the dominant plane of polarization.

Scattering in an Ensemble of Many Particles

In general, when incident light encounters a dust cloud or dusty layer, it interacts with a very large number of particles. In this discussion, the term “particle” refers to an “average particle,” combining the scattering properties of the ensemble of particles. Each of these scatters light onto an even larger number of particles, which, in turn, give rise to further scattering. This makes it possible to consider an average scattering event, involving

Umov Effect, Fig. 2 A ray of light interacting with a single particle and triggering many cascades of multiple particle scattering

an average cascade of secondary scattering, leading to the following simplifying approximations:

1. The total scattering process in the cloud or dust layer can be treated as a very large number of average scattering cascades, added together.
2. A very large number of irregular, randomly oriented particles can be treated, on average, as spherical, isotropically scattering particles in a scattering cascade. Each particle is assumed to have an individual albedo a , which is the same magnitude in all directions.
3. For scattering paths involving only one particle between the light source and the observer, the geometries will be identical and all contributing the same polarization components to the observer, so these polarizations will be additive.
4. The geometries of the secondary scattering events will differ widely and can be assumed random. We assume here there is a very large number of these that will all contribute different polarization effects to the light sent in the direction of the observer, so collectively these will average out and contribute to a randomization of the polarization.
5. That every ray of light ultimately encounters a particle unless it is directly scattered from the source in the direction of the observer.

This scattering scenario is represented in Fig. 2.

Albedo

Light from the source hits a particle. A fraction a of this is scattered in the direction of the observer. This fraction depends on two main factors, firstly the reflectivity of the particle and secondly the geometry of the interaction, i.e., that the light is now being scattered in all directions. We assume that apart from the light directly scattered in the direction of the observer, all rays of light eventually encounter a particle. Then if each scattering event illuminates n particles on average, and each particle sends some light in the direction of the observer, the observed geometric albedo, A , of the cloud or dust layer is given approximately by:

$$A \propto a + a^2 n + a^3 n^2 \dots a^k n^{k-1} \dots \quad (1)$$

where $an < 1$ and we assume the scattering process proceeds ad infinitum, although the contributions to the redirected light eventually become vanishingly small, so the equation becomes:

$$A \propto \frac{a}{1 - an} \quad (2)$$

This geometric albedo, A , is a relative property that refers to the ratio of the reflectance of the

particle to that of a perfectly reflecting Lambertian surface with the same area.

Polarization

The first encounter between the light and a particle has the same geometry as all the other first encounters. However, the large number of ray paths of the encounters with second and subsequent particles will contribute a net randomization of the polarization. We define the degree of linear polarization, P , by:

$$P = \left| \frac{I_y - I_x}{I_y + I_x} \right| \quad (3)$$

where x and y are orthogonal directions with respect to the direction of the scattering plane defined by the location of the source-scatterer-observer. In this case P varies between zero for a randomly polarized (unpolarized) wave and unity for one that is fully linearly polarized.

Since the observer sees the sum of a very large number of cascades, we can assume the first scatter in each cascade yields some level of linear polarization P^* say, but all subsequent scatterings, with their various scattering geometries, yield randomly polarized radiation, the net observed polarization will be weighted for the albedo-related decreases as the cascade is descended:

$$P \propto \frac{P^* + 0 + 0 + 0 + 0 \dots}{a + a^2n + a^3n^2 + \dots a^kn^{k-1} \dots} = P^* \left(\frac{1 - an}{a} \right) \quad (4)$$

So substituting from the albedo eq. (2) where P^* is a constant for the particle population, we have that the observed polarization is decreased in proportion to the contribution of increased interparticle scattering that increases albedo:

$$P \propto \frac{1}{A} \quad (5)$$

This is “Umov’s Law,” and the inverse relationship, where the linear polarization of the scattered light is a maximum for weakly

absorbing, low albedo particles, is known as the “Umov effect.”

Practical Uses of the Umov Effect

The scenario described here involves the integrated contributions of a large number of quasi-random or at least unpredictable events, and according to the central limit theorem, fluctuations in the amplitude and polarization have the properties of a Gaussian process. If the scatterers are non-spherical, but their orientations are random, and there are many of them, the results of the calculation would be similar. Under these conditions it is possible to detect in some cases differences in surfaces, such as in lunar soils, but little can be inferred about the scattering media involved.

However, when the particles are fewer in number or the cascade of scattering is not extensive (e.g., the scatterers have a low individual albedo), the probability density functions of individual fluctuations will deviate from a Gaussian distribution, although they might integrate to this normal distribution, given sufficient time. Some inferences can be made about the scattering particles from observations, but in many cases, the easiest approach is through laboratory measurements and simulations aimed at duplicating the observations. The practical value of the Umov effect has been primarily for evaluating the size of distant celestial objects that appear as a point source to the observer [3].

The Umov effect has also proved useful in investigating the scattering particles producing the zodiacal light, i.e., interplanetary dust particles [5], and the regolith, i.e. dust, gravel, and small rock fragments covering solid rock, on asteroids and the Moon. Other studies include terrestrial aerosols and pharmaceuticals, paints and coatings, and remote sensing through scattering media. It has also been shown to provide a quantitative estimation of the reflectance of small irregularly shaped particles in a two-component mixture, which are commonly found in stratospheric aerosols, desert sands, and thin clouds of cosmic dust [4].

USC Diagrams; Uniform Chromaticity Scales; $Y_u'v'$

Stephen Westland
Colour Science and Technology, University of
Leeds, Leeds, UK

Definition

The coordinates of the CIE 1960 UCS diagram are calculated from the 1931 CIE XYZ tristimulus value or from the xy chromaticity coordinates thus:

$$\begin{aligned} u &= 4X/(X + 15Y + 3Z) = 4x/(-2x + 12y + 3), \\ v &= 6Y/(X + 15Y + 3Z) = 6y/(-2x + 12y + 3). \end{aligned} \quad (1)$$

The 1976 CIE $u'v'$ chromaticity diagram was obtained by stretching the v -axis of the UCS diagram ($u' = u$, $v' = 1.5v$), and the coordinates are calculated thus:

$$\begin{aligned} u' &= 4X/(X + 15Y + 3Z) = 4x/(-2x + 12y + 3), \\ v' &= 9Y/(X + 15Y + 3Z) = 9y/(-2x + 12y + 3), \end{aligned} \quad (2)$$

where, alternatively, $U' = 4X/9$, $V' = Y$, and $W' = -X/3 + 2Y/3 + Z/3$ and $u' = U'/(U' + V' + W')$ and $v' = V'/(U' + V' + W')$.

USC Diagrams; Uniform Chromaticity Scales;

Y_u/v' , Fig. 1 CIE 1960 UCS diagram. Figure by Adoniscik (Own Work) [Public Domain] via Wikimedia Commons

Both the CIE 1960 UCS diagram and the 1976 CIE $u'v'$ chromaticity diagram are associated with the 1931 Y tristimulus value to provide a complete trichromatic specification since $V = V' = Y$.

Historical Development

The 1931 CIE system of colorimetry [1] allowed color stimuli to be defined in terms of tristimulus values XYZ but does not provide a particularly uniform representation of color stimuli in visual terms. If lines are drawn on the CIE 1931 chromaticity diagram that represent equal perceptual steps, then the disparity in the lengths of the lines is as great as 20 times, with the lines in the green region, for example, being much longer than those in the blue region [2].

However, many years earlier it had been suggested, by König, for example, that “it ought not to be difficult in the construction of a chromaticity diagram so to modify the adopted arbitrary assumptions that the separation of two points on it would give a measure for the difference in sensation between the colors corresponding to them” [3]. Following work by Judd, in 1935 a Maxwell triangle yielding approximately uniform chromaticity scales (known as the UCS diagram) was defined by reference to the CIE system, and in 1937 MacAdam developed a rectangular coordinate system based on the simple transformation of tristimulus values. In 1959 at a meeting in

Brussels, the CIE recommended the 1937 MacAdam uv -diagram for use whenever a projective transformation of the CIE xy -diagram is desired to give uniform chromaticity spacing [4]. This space became known as the CIE 1960 UCS diagram (Fig. 1).

If compared with the 1931 chromaticity diagram, the effect of the linear transformation was to elongate the blue-red portions of the diagram and to relocate the white point to reduce the size of the green area. Although not perfectly uniform, the UCS diagram was thought to be an almost optimal transformation from the 1931 space [2] and was deemed to be sufficient for most practical purposes [4]. However, at a meeting in London in 1975, the CIE proposed modifying the UCS diagram and replaced it with the $u'v'$ -diagram stretching the v -axis ($v' = 1.5v$). The resulting diagram was adopted as the CIE 1976 UCS diagram (Fig. 2).

Properties and Current Status

All chromaticity diagrams, whether xy , uv , or $u'v'$, have the property that additive mixtures of colors are represented by points lying on the straight line joining the points representing the constituent colors [5]. However, the CIE 1960 UCS diagram and the 1976 CIE $u'v'$ diagram represent substantial improvements over the 1931 CIE xy chromaticity diagram in terms of the visual uniformity of

USC Diagrams; Uniform Chromaticity Scales; $Y_u'v'_u'$, Fig. 2 CIE 1976 UCS diagram. (Figure by Adoniscik (Own Work) [Public Domain] via Wikimedia Commons)

the spaces. Whereas lines that represent equal perceptual steps drawn on the CIE 1931 chromaticity diagram differ in length by as much as 20 times, the same lines drawn on the CIE 1976 $u'v'$ diagram differ in length by about four times (and over much of the diagram, the difference is not greater than two to one) [2].

CIE 1976 UCS is useful for showing the relationships between colors whenever interest lies in their discriminability. However, it is mainly used for the representation of self-emissive colors on display devices or those produced directly from light sources since the diagram assumes that colors are of equal luminance (this condition is rarely met in practice with reflective surface colors). Note, however, that CIELUV, the first approximately uniform three-dimensional space, is a transformation of the CIE 1976 UCS chromaticity coordinates u' , v' , and Y .

Vantage Theory of Color

Adam Głaz

Department of Modern Languages, Maria Curie-Skłodowska University (UMCS), Lublin, Poland

Synonyms

VT and color

Definition

Vantage Theory (henceforth VT) is a cognition-based model of color categorization proposed by a one-time student of Brent Berlin and Paul Kay, Robert E. MacLaury [1, 6, 8–11]. The model's major tenet is that humans construct color categories as one, two, or occasionally three vantages

(i.e., points of view), a category being an assembly of its vantages.

Vantage Theory Step by Step

Overview

Vantage Theory was proposed after MacLaury and his coworkers had conducted interviews with about 900 speakers of 116 Mesoamerican languages (Mesoamerican Color Survey, part of World Color Survey), later enriched with data from a wide spectrum of world languages. The interviews consisted of three procedures – *naming*, *focus selection*, and *mapping* – and were performed with the use of the Munsell set of color chips, 320 chromatic and 10 achromatic (Fig. 1).

First, in the procedure of naming, the informant was shown the chips one by one in random order and asked to name each. The naming ranges of each color term were then marked on the derandomized array. Next, the informant was asked to choose the focus (best example) of each color term used. Finally, he/she was shown the arranged set without the naming ranges and asked to indicate all chips he/she would refer to with a given term. This process of mapping proceeded in incremental steps, until the informant refused to continue. Thus, the naming range, the focus/foci, and the mapping range of each term were elicited.

Parallelisms between the categorizing behavior of informants and spatiotemporal orientation were

Vantage Theory of Color, Fig. 1 The Munsell color array. The horizontal axis hue, from red to purple, severed in the middle of red at column 40. The vertical axis is for

brightness. All chips at maximum saturation. On the left: ten achromatic colors, from white to black. (© Hale Color Consultants, Inc. Reproduced with permission)

Vantage Theory of Color, Fig. 2 Modeling of the blue category in VT. *Bu* blue focus, *S* attention to similarity, *D* attention to difference

		↗	
2	S	D	breadth, margin

observed, the analogy being drawn in an instinctive and neurally expedited manner. While constructing a color category, a person anchors their cognition in a given dimension of color (hue, brightness, or saturation) and relates color stimuli to that fixed coordinate through similarity or its lack. The fixed coordinate is a categorical equivalence of spatial landmarks, whereas attention to similarity or difference arises by analogy to experiencing relative motion. Constructing a color category is here illustrated with a hypothetical example in Fig. 2.

On level 1, the category is endowed with the blue focus, the starting point for category construction, and a range of color stimuli similar (*S*) to the category focus. When the categorizer starts emphasizing difference (*D*) more than similarity, the category is curtailed at a margin. Through an analogy to motion, VT defines color similarity and difference as reciprocal and gradable, with the endpoints of the cline being total identity and complete disparity. Speakers can shift their attention by moving between the two extremes. Hue (most commonly), brightness (less so), or saturation (rarely) can function as *inherently fixed*

coordinates, whereas *S* and *D* are *inherently mobile*: each type can become the other for immediate purposes of constructing a figure-ground arrangement of coordinates (where the fixed coordinate is the ground or “given” and the mobile coordinate is the figure or “new”). This, however, does not deprive either type of its fixed or mobile status, respectively. *S* and *D* are indispensable, whereas the inherently fixed coordinates depend on the domain of categorization. VT emphasizes hue, brightness, and saturation as important color dimensions based on the implied salience of these perceptual features that is typically found in perceptual experience. If the salience of these dimensions were nonuniform, or if other dimensions took precedent over hue, brightness, and saturation experience, then VT analyses could still be applied to these alternative constructs in a similar fashion.

The ground-to-figure arrangement, in which a mobile coordinate is fixated to serve as ground for the introduction of a new value, is called a *vantage*. Crucially for the categorizing process, there may be two or sometimes three vantages (points of view) on a category, the category being the

Vantage Theory of Color, Fig. 3 Modeling of the cool category in VT

Vantage Theory of Color, Table 1 Characteristics of the dominant and recessive vantages. Elemental colors are “the purest, most intense perceptions” of red, yellow, green, blue, white, and black [8, p. 467], although black

and white are traditionally not treated as colors. Elemental colors have their specific locations in the Munsell array, cf. Fig. 4

Dominant vantage	Recessive vantage
Greater number of chips covered	Smaller number of chips covered
Range more concentrated – over a more compact area	Range more dispersed – over a larger area
Focus more centralized relative to elemental colors	Focus less centralized relative to elemental colors

assembly of the vantages that compose it. In space-time, the same event involving motion is perceived differently depending on one’s location (e.g., on a train vs. while standing by the track). As an example of point of view in color, consider the hypothetical cool category in Fig. 3, named with two terms, *x* and *y*. The two points of view are the blue-focused similarity-based *dominant* vantage and the green-focused difference-based *recessive* vantage. They are characterized by a reversal of coordinates that swaps an emphasis on similarity to the focus with an emphasis on difference from the focus.

In the blue-focused dominant vantage, the emphasis on *S* is juxtaposed with *Gn* (green), the second focus of the category, which is then juxtaposed with *D*. The recessive vantage starts with the *Gn* focus. However, here the categorizer first establishes the boundary of the vantage by concentrating on difference vis-à-vis a blue category focus, *Bu*, which is introduced as a mobile coordinate on level 2 but returns to its inherently fixed capacity on level 3. There, it is treated as (weakly) similar to *Gn*, the process defining the range of the vantage.

Together, two vantages as points of view are the way VT models the complexity of categories that is seen in the empirical data. According to VT analyses, in such data one can explain the existence of cool or warm categories as the cognitive trading off of emphases of similarity and difference.

The most important differences between the two vantage types are listed in Table 1.

Figure 4 illustrates these differences with the cool category in Zulu.

The dominant *hlaza* names 62 chips, as opposed 56 for the recessive *kosazana*, but it only spans 20 columns vs. 25 that *kosazana* does. *Hlaza* is focused in G28, which is very near elemental blue in F29, whereas *kosazana*’s first focus (the second focus being disregarded for the present purposes) falls on C17, as many as three rows above elemental green in F17 (interestingly, elemental green in F17 is named with the blue-focused *kosazana*). These visible effects (entailments) of the two points of view on the category are like a person’s spatiotemporal location being determined through reference to stationary and moving objects.

Vantage Theory of Color, Fig. 4 Naming and focusing of the cool category in Zulu (Bantu group, Niger-Congo family). *Lighter hatching*, blue-focused dominant *hlaza*; *darker pattern*, green-focused recessive *kosazana*. *Dark*

squares: elemental blue (F29) and elemental green (F17). *Dark ovals*: foci for *hlaza* (G28) and *kosazana* (C17). (Figure received by the author from Robert E. MacLaury)

Semantic Relations Between Vantages

In addition to modeling color dimension relations as just described, there are also three major types of semantic relations between the dominant and recessive vantages (*near synonymy*, *coextension*, and *inclusion*) that influence the ways color is ultimately categorized. These are “segments of a continuum, not discrete kinds of relation” [8, p. 112].

In near synonymy, the vantages are very much alike in terms of focus selection and range, and the differences are minimized. An example is the warm category, termed *he* and *lu*, constructed by a speaker of Jicaque (or Tol), an isolate spoken in Honduras [8, p. 123].

Coextension is a unique kind of relation and requires more attention. The fullest account can be found in [8]; see also [6, 9, 10]. Coextension was first observed in the warm category of Uspantec (Uspanteco), a Mayan language of Guatemala, and later in many interviews in Mesoamerica and elsewhere. The first four characteristics below are more common than the remaining ones, though all are subject to some degree of variation:

1. One category is named with two different root terms.
2. Each of the two terms is focused in reference to a different elemental hue.
3. The mapping of each term encompasses the focus of the other.

4. There is substantial overlap of the mapping of the two terms.

The more variable features are:

1. Mappings of the two ranges progress in opposite directions.
2. Naming ranges are intermixed, so that chips named with one term may be surrounded by those named with the other.
3. Foci of one or sometimes both terms are polarized, moderately when a term is focused between the category margin and the relevant elemental hue, in extreme cases when the focus falls outside the naming range of the term.

Figure 5 shows coextension in an early phase (closer to near synonymy than to inclusion).

Another example is the Zulu cool category in Fig. 4.

Coextension cannot be explained solely in terms of perceptual dimensions; instead, it is the observer who “assumes opposite slants on the same sensations and names them differently from each angle” [8, p. 113]. Coextension can thus be thought of as variable semantic bias or a strategy. This provides a strong argument in favor of subjectivity and speaker agency in categorization and meaning construction.

In inclusion, the naming and/or mapping ranges of the subordinate (recessive) term fall inside that of the superordinate (dominant) term.

Vantage Theory of Color, Fig. 5 Coextension in an early phase. Warm in Tzeltal (Mayan, Tzeltalan), Paraje Nabil, Tenejapa, Chiapas, Mexico, male 65, 1980, (a) naming and foci, (b–c) mappings. (Figure received from Robert E. MacLaury)

This happens when, as a result of strong attention to *D*, one of the ranges tends to “drift away” but both still share fixed cognitive coordinates. An example is the warm category in a speaker of Aguacatec (Awakateco), a Mayan language of Guatemala ([8], pp. 195–196, cf. also 10).

When the strength of *D* rises even more, the cognitive link between the vantages is broken, and the two ranges separate: inclusion becomes *complementation*, a relation between the dominant vantages of distinct categories. Extreme value of *D* causes category split.

Finer Distinctions

VT models finer aspects of color categorization as *frames*, *stress*, and *viewpoints*.

A frame is a closed system of interdependent parameters, such as emphases on *S* vs. *D*.

Occasionally, three vantages on a category are constructed, e.g., in the warm category in Aguacatec [8, pp. 115–116]. In a non-framed analysis, the three vantages are called *dominant*, *recessive*, and *ultra-recessive*, but a framed analysis links the dominant and the recessive terms (the red-focused *k'aq* and the yellow-focused *q'an*) into frame I, while the recessive and the ultra-recessive terms (*q'an* and the brown-focused *sq'inko'x*) constitute frame II. In frame II, the relationship between the recessive and the ultra-recessive term is analogous to that between the dominant and the recessive term in frame I. Thus, the terms *dominant*, *recessive*, and *ultra-recessive* are relative rather than absolute.

Stress is mental proximity to either the fixed or the mobile coordinates in a vantage. In the color domain, stress may be put on hues or on relations

between them. In the former case, one of the hues may “draw” the category to itself – this is called *skewing* [7]. The category may thus divide, as happened in the Mayan language of K’ekchi (Guatemala, Belize and El Salvador) [11, pp. 128–129]. In the latter case, focus placement may be random, foci may substitute for each other, and mismatches may be observed between naming ranges, foci, and mappings both for a single speaker and between informants. Informants may maintain the dominant-recessive pattern without preference for which hue is dominant or recessive: the pattern itself seems to be more important than the hues on which it is based. Stress on mobile coordinates has been noted in Mazatec (or Huautla, Oto-Manguan, Mexico) [8, 11] or Mam (Mayan, Guatemala) [8, pp. 294–306]. The behavior is consistent and appears chaotic only for speakers used to stressing fixed coordinates, as those of English.

Viewpoints are gradable degrees of subjectivity/objectivity with which a person constructs a category or conceptualizes an object or scene [8, 10, 11]. The notion has been found useful in modeling several Mesoamerican languages (Nahuatl, Cakchiquel, Northern Tepehuán, Quiché, Chinantec, or Lacandón). It is a good example of how VT can be extended beyond color: the conception has been applied in several accounts of linguistic behavior [4, 5, 8].

Other Notions

Although originating in the color domain, VT is claimed to have universal application and pertain to categorization at large. Aspects of VT not discussed here include, among others, brightness-based categories; full vs. partial inversion of coordinates; submerged vs. reflective vantages; the role of *S* and *D* in categorical evolution; the flip-flop, or oscillation, of color term meanings; dual and triple foci; non-discriminatory vs. analytic vs. synthetic thinking; the spotlight effect; and more [6, 8, 10]. On a more general level, VT relates to the question of linguistic relativity, representing a non-Whorfian stance but one which endorses variety in linguistic behavior.

The variety, however, occurs within a cognitively universal but plastic mechanism of categorization [9].

Vantage Theory’s Unique Contributions

With VT, MacLaury has contributed to research on color categorization in three major ways. First, he has redefined the notion of a category, traditionally identified with a color term. In VT a term names a vantage on a category, and there may be one, two, or occasionally three such vantages. Second, he has identified, defined, and modeled coextension as a relation between vantages that at face value appears chaotic or indicative of errors in data elicitation. Third, VT stresses individual variation and personal preference in color categorization. It is an attempt to model that variation and reconcile it with both the classical perceptual constructs of hue, brightness, and saturation and cognitive emphases on similarity and difference. Vantages on categories help to systematically explain how the same stimuli may be differently interpreted by different individuals but also how the same individual might interpret the same stimuli as different on different occasions.

Future Directions

So far, with few exceptions, VT has remained largely dormant though full of potential. In order to utilize this potential, it is proposed that the theory should be made more accessible to the color research community by producing textbook-type publications (a noteworthy precedent is Sect. “9.3” of [2], though it remains isolated and rather limited in scope). It may and should provide more insight into the linguistics of color and color naming, as indeed it has in the past [3, 12]. Also, VT as a theory is open to extension and elaboration.

VLC

Definition

Light in free space from LED luminaires used simultaneously for illuminating the space and wirelessly transferring data into that space.

Principle of Visible Light Communication

In a visible light communication (VLC) lighting system, data can be encoded by switching the system's LED luminaires on and off at high frequency, i.e., modulating the intensity of light. In the VLC practice, the light is not switched on and off entirely but dimmed and not dimmed. So, only the top part of the intensity is modulated, resulting in only a small ripple in intensity (Fig. 1). In this way, the illumination level is hardly affected by the modulation. Figure 2 shows the functional scheme of a VLC system. It exists of a LED luminaire with a modulator that codes the light and a photodetector, somewhere in the lighted space, with a demodulator to decode the data. The photodetector can, for example, be a simple camera of a smartphone. A smartphone app can do the demodulation. For PCs, laptops, and other smart apparatus, low-cost dongles are available with an integrated photodetector and a demodulation/decoder processor.

Of all light sources, only LEDs are suitable for visible light communication. This is because the luminous flux of LEDs varies nearly instantaneously with a variation of current through the LED. Only in this way, light can be modulated at high speed, i.e., the light “on” and light “off” (or “not-dimmed” and “dimmed”) condition can

Visible Light Communication, Fig. 1 Example of encoding by modulating the top of the luminous intensity of a LED luminaire

Visible Light Communication, Fig. 2 Visible light communication (VLC) functional scheme

be produced at extremely high frequencies. The response time using incandescent and gas discharge lamps is too long. With phosphor LEDs, the response time is somewhat longer than with non-phosphor LEDs, but still short enough for VLC with moderate to high transfer rates (up to 100 Mbit/sec). The phosphor-converted components of the light of

a white (blue-pumped) LED can be filtered with a narrowband blue filter placed in front of the photo-detector. In this way, only the light of the blue LED, with near-zero response time, can be used for VLC. In this way, white phosphor LEDs can have the same ultrahigh transfer rates as non-phosphor LEDs (up to more than 1 Gbit/sec). So, commercial,

off-the-shelf LED luminaires can be used for visible light communication.

To ensure that the modulation does not interfere with the illumination quality and to permit for data communication under all dimming conditions, more sophisticated modulation techniques are often used. Light reaches the photodetector not only directly but also indirectly. It makes the demodulation technique even more complicated. The method must permit for making a distinction between the direct and indirect light components. Such a method also helps to solve the problem of direct light sometimes being intercepted by objects or persons in the space, resulting in the photodetector having no longer a direct view of the light source. In such a situation, with appropriate modulation techniques, the reflected light can keep the communication going on. Interference by daylight and other ambient light sources also puts requirements on the modulation and demodulation technique.

As light does not penetrate through opaque walls and thus all communication is contained within the room, the security of VLC is higher than with RF communication.

Download-Only Systems

Many VLC applications concern the use of VLC as a tool for pushing information, i.e., downloading only or broadcasting. Reasons for using VLC instead of Wi-Fi (radio frequency) are no congestion as with the Wi-Fi bands, lower installation cost, lower energy consumption, higher security, no electromagnetic interference, and higher data transfer speeds. New applications using data pushing have emerged and will continue to emerge for situations where the installation of RF systems requires too much effort. Some examples are described below.

Personal Movie System in Planes

The LED reading lamp in planes can be used to transfer sound and video for the in-flight personal sound and movie system. Since dedicated communication cables are no longer needed, the robustness of the system increases considerably, while the fuel consumption of the plane decreases because of the eliminated weight of cables.

Indoor Navigation

A GPS (global positioning system) uses the signals received from satellites at different positions to determine the location of the GPS. The satellite signals are not strong enough to penetrate buildings. Consequently, GPS can only be used outdoors. With a VLC system, it is possible to make the LED luminaires used for the lighting in a building, acting similar to the satellites in a GPS. Such a system is either called a visible light positioning (VLP) system or an indoor positioning system (IPS). The satellite signals received by a GPS are used to calculate the distance of the GPS from the known locations of the satellites. In an indoor VLC navigation system, data transferred by the luminaires contain an identification of each luminaire. With this information, the location of each luminaire can be determined from that data so that, in turn, the position of the camera can be calculated.

Light Itself as Sensor

By adding to the luminaires of a VLC system photodetector, it is possible to measure the time of flight, ToF, of light from the moment it leaves a luminaire until its small, reflected component returns at the luminaire from which it originated (Fig. 3). In this way the VLC system can be used for scanning a room to pinpoint the location of objects in an area: light as a sensor, also referred to as time-of-flight, ToF, sensor.

The contours of objects and even the pose and movements of persons (sitting, standing, lying, or walking) can be determined with time-of-flight sensors [1, 5, 7]. Sudden changes in the pose from standing to lying can be recognized as a person who has fallen. It can subsequently set an alarm. This emerging feature of light as a sensor, once technically perfected, would be well suited for use in healthcare environments and homes of (older) singles living alone. Many other applications can be thought of.

Combined Down-Upload Systems (Li-Fi)

VLC can be extended into a bidirectional communication system with a down- and uplink. Harald Haas of the University of Edinburgh introduced at

Visible Light Communication, Fig. 3 Light as a sensor. The time of flight of encoded light of a luminaire leaving the luminaire until its reflected light returns at the luminaire is used to determine the location of an object in a room

TEDGlobal in 2011 the name Li-Fi (light fidelity) for such bidirectional systems [3]. It is a much-needed alternative for, or a complement to, the more and more congested Wi-Fi wireless RF communication system. Of course, it would be disturbing if for the uplink visible light is used. Disturbing light beams would be radiating from all connected devices in the room, such as PCs, laptops, and smartphones. So, while with Li-Fi the downlink indeed uses visible light, the uplink uses either invisible infrared or Wi-Fi. Dongles for use in PCs and laptops with an integrated photodetector and infrared or Wi-Fi source have been introduced. A room connector must be used to interconnect Li-Fi networks in adjacent rooms. It sends data from one side of a wall to the other side through an optical fiber. In most data communication situations, much more data is downloaded than uploaded. Therefore, even by using a

Li-Fi system with the upload link using Wi-Fi, still, a substantial contribution to reducing the congestion of Wi-Fi networks is obtained [2]. Because of the explosive use of the Internet of things, the limits of the capacity of Wi-Fi will be reached quickly. It makes a fast roll-out of Li-Fi, with its virtually infinite bandwidth, indispensable. It may be expected that this fact, together with the energy efficiency, security, and ease of installation of Li-Fi systems, will be a strong drive for the fast development of the global Li-Fi market.

The Li-Fi market will certainly not only consist of lighting installations with the dual function of illumination and data transfer. Dedicated communication-only installations using laser LED beams (in the infrared wavelength region) are also being developed where transfer speeds of 100 Gbits/sec are foreseen [4, 6].

[Age-related changes of human seeing abilities](#)

Definition

Aging of the human eye and its influence on seeing abilities with regard to brightness, color, spatial resolution (visual acuity and legibility), visual field, and glare.

Senescent Changes in the Visual Organ

Visual information accounts for about 70% or 80% of sensory information in human beings. Like other sensory organs, human vision has senescent changes for most of the parts in the visual system, and these make quality of seeing degraded to older people.

Figure 1 shows a simple sketch of human eye together with major structural changes with age that affect perception of vision. Light from the external world enters into the eye through the lens and reaches onto the retina that covers the back of the eyeball. Two age-related changes occur at the lens; one is loss of elasticity and the other one yellowing and clouding of the lens. The former one brings on less accommodative power of the lens and consequently results in loss of fine-tuning of visual image, i.e., visual acuity, especially at near point less than 1 m of viewing distance. The latter one makes color appearance yellowish and hazed and also makes visual acuity worse due to degraded retinal image by scattered lights. Reduction of light transmittance also occurs in vitreous humor in the eyeball by absorption and scattering of light which also reduces performance for most of the visual functions.

In the retina, photoreceptors that are densely packed in the retinal layer decrease their density with age, and this brings the reduction of visual acuity too and furthermore, particularly in the peripheral retina, less sensitivity to temporal changes of lights, such as flickering or flashing lights. The decrease of photoreceptors in peripheral retina also results in narrowing visual field and makes the detection of lights presented in periphery more difficult for older people.

Visual responses generated in the retina are finally transferred to visual cortex in the central brain. Some senescent changes also occur in this

Vision and Age, Fig. 1 An illustration and major senescent changes of the eye

pathway of neural transmission, and consequently the quality of visual responses is degraded more or less.

Senescent changes of human visual system and resulted performance changes for older people were summarized in some scientific literature [1–3] and in documents for the application fields of lighting and visual signing [4, 5].

Following are major functional changes of vision caused by the senescent changes of the eye described above.

Spectral Sensitivity of the Eye and Luminance

Spectral Sensitivity

Human visual system responds to electromagnetic radiation ranged in wavelength about 400–700 nm called visible range (correctly defined as 380–780 nm by CIE). Most sensitive part is at around 555 nm (green-yellow), and the sensitivity decreases gradually toward both the shorter and the longer end of the visible range. Out of this range, i.e., the ultraviolet range (shorter than 380 nm) and the infrared range (longer than 780 nm), the eye does no longer respond to and cannot see the radiation. The general shape of this sensitivity curve along with the wavelength is a bell-shaped smooth curve with a peak at 555 nm.

This spectral sensitivity of the eye changes with age. Due to the yellowing of the lens mentioned in the previous section, spectral lights in the shortwave region (about 400–500 nm colored violet or blue) are partly absorbed by the lens and do not fully reach to the retina, and consequently the shortwave lights become less sensitive to the eye. The absorption gradually increases with age, and the violet or blue lights look darker to older people [6, 7].

Figure 2a shows the spectral sensitivity curves of the eye for seven different age groups from teens to 70s in decade steps all being normalized to 1.0 at its peak sensitivity [7]. It is clear that sensitivity at the shortwave region gradually decreases with age, and the difference reaches to more than one logarithmic unit between teens and 70s at the short end of the spectrum. This practically means brightness for a blue lamp or a blue LED display that generates the shorter wavelengths looks much darker to older people compared with young people.

Luminance Contrast for Older People

Spectral sensitivity is a fundamental function to estimate brightness of a light or an object which is technically called luminance in the field of photometry, i.e., the visually meaningful metric of light. This luminance, denoted as L , is defined by CIE as follows:

Vision and Age, Fig. 2 (a, b) Spectral sensitivity of human eye for seven age groups from teens to 70s [7] and a calculation example of contrast for a blue sign presented on a dark-brown background [8]

$$L = K_m \int L_{e,\lambda} V(\lambda) d\lambda \quad (1)$$

where

K_m maximum efficacy (683 lumen/watt)
 $L_{e,\lambda}$ spectral radiance (watt/m²·sr)
 $V(\lambda)$ CIE standard luminous efficiency (spectral sensitivity of the eye)

As expressed in this equation, luminance is a total amount of radiation weighted by visual sensitivity $V(\lambda)$. However, as $V(\lambda)$ changes with age (see Fig. 2a), the luminance changes its value accordingly for people with different ages.

Figure 2b shows an example of the calculation. Given that spectral radiation for a blue sign and a dark-brown background as shown at the top of Fig. 2b, relative luminances of them for observers in their 20s and 70s, for example, are calculable using sensitivity curves of 20s and 70s, respectively (the second curve from the top and the bottom one in Fig. 2a), and luminance contrast between the blue sign and the background is obtained. The results are 2.07 and 1.13 for the young and older observer respectively, which

means that the same sign is seen in good contrast for the young person but in lower contrast for the older person. With this way of calculation, contrast of any colored sign or object can be evaluated accurately. This is called “age-related luminance contrast.” To avoid any confusion with the already standardized luminance by CIE using $V(\lambda)$ (the standard luminous efficiency curve), this calculation only applies to know the contrast, i.e., relative relationship of luminance [8].

Color Perception

Color Appearance

Due to the yellowing of the eye lens with age, all the perceived colors look more or less yellowish for older people. This color shift is not so vivid nor conscious due to the adaptation or constancy of the visual system. In some case, however, when we try to discriminate a yellow sign on a white background or vice versa, for example, it becomes harder for older people to discriminate them.

Scattering light inside the eye (lens and vitreous humor) also changes color appearance. Scattered lights falling on the retina make all the colors

desaturated like white noise and consequently reduce the vividness of color (saturation). Due to this desaturation effect and together with other neural pathway changes with age, the discrimination of color becomes worse with age in a whole perceived color space [1].

Color Category

Human color space consists of a large variety of colors that distribute in a three-dimensional space of hue, lightness, and chroma or saturation. Recent psychological studies on color perception have found that these colors are perceived into a limited number of groups in higher central brain, namely, color category. For example, a purplish red and an orangish red are both perceived as a family of red group regardless of the small difference. This concept can be usefully used for color combination in a manner that any two-color combination made from different categories becomes differential or, on the contrary, any two colors picked up from the same category are easily confused. Data on which color belongs to which category and how the aging affects the category is a critical issue for using this concept and application.

Figure 3a shows the data for color category for young and older people expressed in Munsell Color Space measured on the bases of subjective evaluation of color similarity for a total of 13 fundamental colors as a focal color of each category [9]. Most important and interesting point of the color category data is the fact that span of the category is smaller for older people than that for young people for almost all the fundamental colors. This is a feature contrary to color discrimination. One of the reasons for this might be the desaturation of colors for older people caused by interocular scattering of light. Vivid colors reduce their saturation and shrink their areas in the color space. Figure 3b is an example of how to apply the color category data. Coloring of six traffic lines is taken as an example. The six lines are colored with six different colors each of which are picked up from color categories that do not overlap each other in the color space. This makes the color combination discriminable to older people if the category data of older people (solid lines in Figure 3b) apply. Any color belonging to the

span of category is allowed to use for this color combination with no need for picking up exact colors predetermined, which is a practical advantage for creating color combination.

Contrast Sensitivity

Contrast sensitivity is a visual ability to perceive a difference between any two adjacent fields either in luminance or in color, or both, such as an edge between a wall and a door, marking on steps, characters or symbols on an extended background, etc. Visibility of signs and displays depends on the contrast of their contents, and particular care or attention is required for a better contrast.

As shown in Fig. 4, contrast sensitivity of human visual system is usually specified with a periodic pattern like a sine- or a rectangular-wave pattern of variable number of cycles per degree (cpd) with luminance modulation between a darker ($L_{\min}$) and a brighter ($L_{\max}$) part which are used as a metric of contrast such as Michelson contrast.

The right side figure is one example of contrast threshold data, i.e., minimum contrast to detect a grating pattern. The contrast threshold is minimum (i.e., most sensitive) at around 2 or 3 cpd and increases toward the higher and the lower spatial frequency region. Age-related difference is seen at the higher-frequency region meaning that older people need higher contrast to see a spatially fine or detailed pattern.

Some studies on contrast sensitivity function (CSF), which is a reciprocal of contrast threshold as a function of spatial frequency, have revealed there is a clear age-related decline of sensitivity with age at higher-frequency region as demonstrated in Fig. 4, which are summarized in CIE Report [4].

Visual Acuity and Legibility of Characters

Visual Acuity

Visual acuity is an extent to which human visual system can resolve spatial details of visual stimuli.

(a) Color category data

Vision and Age, Fig. 3 (a, b) Spans of color category for fundamental colors and an application example. (Redrawn from Ref. [9] and ISO24505:2016 [10]. Coloring is image only)

Vision and Age, Fig. 3 (continued)

It is defined quantitatively, in case of decimal acuity, as a reciprocal of minimum visual angle expressed in minutes to detect a gap of a circle (called Landolt C) as follows:

$$V = 1/\Delta\theta \tag{2}$$

where

- V visual acuity
- $\Delta\theta$ minimum detectable visual angle in minutes of arc

There are three major critical factors that affect visual acuity: age, viewing distance, and luminance. Figure 5a shows how visual acuity changes with viewing distance, and Fig. 5b demonstrates luminance effect, both for different age groups from teens to 70s [12]. It is clear from Fig. 5a

that the visual acuity at near distance less than 1 m remarkably decreases for age groups over 40 years indicating that reading out fine-printed information such as maps or newspapers at hand is much harder for older people.

With regard to luminance effect (Fig. 5b), visual acuity becomes gradually worse as luminance decreases which shows discrimination of visual signs at a darker condition becomes difficult for both young and older people. It should be noted that the luminance change affects all the age groups in the same manner and no remarkable difference in the relative course of luminance effect is found among the age groups.

Legibility of Characters

A visual task that is most related to visual acuity is identification of characters or reading sentences, i.e., legibility or readability, where discrimination

Vision and Age, Fig. 4 Definition of contrast and an example of the contrast threshold data for observers in their 10s and 70s. (Data redrawn from Ref. [11])

Vision and Age, Fig. 5 (a, b) Visual acuity as a function of (a) viewing distance and (b) luminance for seven different age groups [12]

of fine visual pattern is required. Smaller font size is sufficient if the visual acuity is higher and, on the contrary, larger font is required for lower visual acuity.

Figure 6a, b are examples of how much font size is required to see at moderately bright level (100 cd/m²) for Japanese characters of phonetic signs (including Arabic numerals) and simple and complex Chinese characters [12]. The data show

the minimum legible font size, under which the characters are not legible, for young and older people at 0.5 and 2.0 m of viewing distance. At the short distance, minimum legible font size for young people is about 4 points in average, but at the same condition, older people require about 12 points, i.e., three times larger than that for young people. This age-related difference becomes smaller at the longer viewing distance

Vision and Age, Fig. 6 (a, b) Minimum legible font size for Japanese characters. (Redrawn from Sagawa et al. [12])

of 2 m (Fig. 2b). It is also clear from these data that the size for the sans-serif font is slightly but consistently smaller than that for the serif font for almost all the conditions indicating that the sans-serif font is more legible than the serif font when the viewing condition is identical.

Practically it is useful to estimate the minimum legible font size at any viewing condition where age, viewing distance, and luminance are varied. An estimation method for the minimum legible font size has been provided by ISO [13]. Some calculated examples at a constant luminance condition, for example, at the 100 cd/m² level, are shown in Fig. 7a, b as a function of viewing distance for different age groups.

Visual Field

Human vision covers a wide range of visible field, not only a center field around visual axis but also a peripheral field that extends to almost 180° in front of the eye. This visible range is called visual field, the size of which is usually expressed in visual angle in degree from the central visual axis regardless of viewing distance. The visual field is functional, and the size of which depends on what we see or what we do with vision. This is defined as

useful field of view or useful visual field. The useful visual field for simple detection of a light, for example, is rather wide, but the field for complex visual task like reading letters becomes much smaller being limited to the central part of the visual field.

The size of useful visual field is affected by age. Due to the decrease of density of photoreceptors at peripheral retina with age, the visual field size is reduced for older people compared with young people. Figure 8 shows the experimental data on useful visual field for detecting a target with different luminance contrasts, target colors, and adaptation levels [14]. Visual field size reduces with reduction of target contrast, depends on target color, and reduces with adaptation level from the photopic to mesopic level, and it is clear that older people consistently show smaller visual field than young people for all the viewing conditions. Traffic signs or emergency signs could be missed to see by older people if they are presented to the peripheral visual field.

Characteristics of visual field in ordinary scene are much more affected by cognitive aspect of visual information such as attention, searching, memory and learning, etc. Understanding of visual cognition and its aging effect in relation to useful visual field, however, are not well-known yet and will require further studies in the future.

Figure 7 (a, b) Minimum legible font size at the luminance level of 100 cd/m² as a function of viewing distance for different age groups. (Redrawn from ISO 24509 [13])

Figure 8 Useful visual field for detecting a target on a uniform gray background with variable contrast, color of the target, as well as adaptation levels. (Redrawn from the AIST data [14])

Glare

It is well-known that older people are more sensitive to glare than young people due to the light scattering in the ocular media that increases with age. Though it is obvious from previous studies that the physical light scattering in the ocular media of the eye increases with age [15], psychological data are scarce that show the age-related increase of subjective feeling of glare. Further studies and data collection to confirm the aging effect on psychological evaluation of glare are required.

Summary

Studies on vision and age have been conducted extensively over the past few decades, and basic knowledge has been cumulated to some extent, partly in response to the increasing social need for universal design or accessible design. The knowledge of aging effects on vision could be applied to the design of lighting, visual environment, and signage for better and safer life of older people. Further basic studies are emerging into a more challenging field of vision-based cognitive science and aging effects toward full understanding and application of human visual information processing.

Event Related Potential; ERP; VEP

Definition

The visual evoked potential (VEP) is a means of extracting from the spontaneous electrical activity in the brain, electrical changes that are directly related to a specific brain action. It is a means of analyzing the Electroencephalogram (EEG). The event-related information ("signal") is extracted from the overall electrical activity ("noise") by some form of correlation. Usually, repeated samples of EEG are triggered by a particular event (e.g., an abrupt visual change) and averaged together. Because this event causes a particular type of brain response, at a predictable time, the process of averaging these time locked responses accentuates the event-related signal and smoothes out any uncorrelated activity. By using a stimulus that only contains time-locked changes in color, the VEP can provide an indirect measure of color information processing in the brain.

Scalp-Recorded Electrical Signals from the Brain

The brain is constantly generating large amounts of noisy electrical signals, emanating from the

vast number of neurones firing at any given time. This ever-changing activity can be recorded by attaching electrodes to the scalp. The spontaneous activity, known as the Electroencephalogram (EEG) (<http://www.springerreference.com/docs/html/chapterdbid/116485.html>), reflects all the current motor, sensory and cognitive processes. If we wish to study brain activity that is related to a particular function (e.g., hearing or seeing) we can isolate that part of the EEG which occurs in response to specific stimulation by sounds or visual stimuli. In order to elicit such stimulus-related visual response, known as the visual evoked potential (VEP), it is necessary to cause a *change* in the stimulus, since the evoked potential is actually a measure of a *change* in electrical activity.

The crudest form of visual stimulus would be an instantaneous flash of light. This is rather like taking a sledgehammer to crack a nut, and is not very well suited to probing specific types of brain function. However it is often used clinically to get some idea of whether there is a gross connection between the eye and the brain, for instance in

Visual Evoked Potentials, Fig. 1 VEP elicited to a black and white checkerboard with each square measuring 1 degree of visual angle. The checks reversed every 250 ms. The key wavelets are negativities at about 75 and 135 ms, and a positivity at about 100 ms. The waveform was produced by averaging together fifty 250ms samples of EEG, each of which was triggered by an identical event (the instantaneous reversal of the checkerboard). Timings are relative to this trigger event

cases of cortical visual impairment. Patterned stimuli are more frequently employed; typically these are carefully specified repetitive patterns such as checkerboards or gratings. These have to be temporally modulated to elicit a response; usually this takes the form of pattern reversal or pattern onset-offset. Taking the example of a black-white checkerboard, in pattern reversal mode the black and white squares exchange places at fixed intervals, every few hundred milliseconds. In on-off presentation, the checks are replaced periodically by a blank gray screen so that there is no change in space-averaged color or luminance. It is crucial that artifacts are avoided: an overall luminance change between the two phases would itself elicit an evoked response, but this would have no relationship to the spatial content of the stimulus. Figure 1 shows a typical response to a reversing black and white checkerboard; this has a widespread use in clinical ophthalmology and neurology.

The electrogenesis of the evoked potential is not well understood, but the signals recorded from an electrode placed on the scalp above the occipital (visual) cortex are said to reflect mainly the activity of early visual areas V1 and possibly V2. The signals are recorded using a differential physiological amplifier, which takes the difference between the potential at the “active” site (e.g., the occiput) and a second electrode placed at a

Visual Evoked Potentials, Fig. 3 Combining red and green gratings in phase to make an achromatic (yellow) stimulus and out of phase to make a chromatic (red-green) grating. Also shown is the offset phase when contrast is zero; note that this is the same for both stimuli

nonvisual or “reference” site (e.g., the vertex or an earlobe). In fact, the terms “reference” and “active” are misnomers as it is possible to record some level of visually related activity from anywhere on the scalp. An alternative name for this

Visual Evoked Potentials, Fig. 4

VEPs to a range of red-green ratios. The isoluminant response (when, for this subject, $RGR = 0.5$) is shown in red. The gray plot is the equivalent achromatic VEP, recorded to a yellow/black grating. Note that there is no significant difference between this response and those to the red/black or green/black gratings

montage is unipolar. A bipolar electrode montage places both electrodes over the same cortical area, a few cm apart. This generates smaller signals but has the advantage that distant sources of electrical “noise” tend to be of the same magnitude at both electrodes and are therefore not as readily recorded using a differential amplifier.

Chromatic Evoked Potentials

A spatial stimulus is defined in terms of many parameters, including its size (how many degrees of visual angle it subtends on the retina), the pattern type (e.g., sinusoidal or square-wave

gratings), its periodicity or spatial frequency (i.e., number of spatial cycles per degree of visual angle), the type of temporal modulation (e.g., sinusoidal or square-wave) and temporal frequency (number of temporal cycles per second). In order to elicit a chromatic response, the stimulus has to vary in color alone, in both spatial and temporal domains. It is important to achieve activation of color opponent mechanisms (see Fig. 2).

The simplest and most well-established method is to use a sinusoidal grating composed of two colors, say red and green (Fig. 3), which has been adjusted for each subject so that it is isoluminant. This means that, for an individual,

there is no change in luminance across the stimulus, but only a change in color or chromaticity. This is usually achieved with a psychophysical procedure such as heterochromatic flicker photometry (HFP), in which the two colors are exchanged at a fairly high rate (about 16Hz), and their luminance reciprocally adjusted until the perception of flicker (which results from residual luminance contrast) is minimised. In on-off mode, the pattern would be replaced with a plain yellow field of the same space-averaged hue and luminance.

In Fig. 4, a series of VEPs are shown in which luminance contamination is present in varying quantities. At isoluminance (the middle trace, shown in red), the onset response takes on a different shape, the achromatic positivity (seen at top and bottom of the figure) being replaced by a chromatic-specific negativity [1–5]. This achromatic-chromatic difference is not seen when checkerboards or reversal presentation are employed, and this is possibly because these stimuli are not optimal for the chromatic visual system, which, at least for red-green stimuli, is handled by the parvocellular (P) visual pathway [6]. The P pathway is dominated by sustained nerve fibers, whilst reversal favors transient responses, and perhaps therefore activates preferentially the magnocellular system [7].

Although red-green stimuli are relatively easy to generate on a graphics display using the red and green primary phosphors, they usually contain significant contrast in both red-green and blue-yellow color opponent pathways. Since these properties are handled by different retino-cortical pathways (respectively the parvocellular and koniocellular streams), it is desirable to optimize the stimulus so that it activates a particular pathway. Physical colors are often represented in a 3-dimensional space, an example of which is given in Fig. 5. See [► [Psychological Color Space and Color Terms](#)] for more on color spaces. The two component colors of the stimulus are selected from this space, forming a vector. This vector can be located at a particular orientation in order to restrict activation to one channel (say blue-yellow), whilst keeping the others (red-green and luminance) constant. In Fig. 6, a range of VEPs have been recorded to onset of chromatic stimuli which all lie on the isoluminant plane in MBDKL space [8, 9]; thus the luminance channel is held constant. The vector has been rotated for each successive recording so that at some point it passes through each color channel. When the chromatic axis (ϕ) is 0–180°, the stimulus is modulated along the L/M cone axis (“red-green”); when $\phi = 90$ –270°, it preferentially activates the S-cone axis (“yellow-blue”). 10 additional recordings have been made at intermediate

Visual Evoked Potentials,

Fig. 5 MBDKL color space; with thanks to Prof D. McKeefry

angles where one would expect a mixture of red-green and blue-yellow signals. The blue-yellow VEP, which taps the sluggish koniocellular pathway, has a much longer latency (time from onset of the stimulus to peak of the component) than the M or L-cone mediated responses (see Fig. 6 inset).

Limitations

There are a few factors which need to be taken into account when recording chromatic evoked potentials. Firstly, these stimuli may be contaminated

by luminance information due to chromatic aberrations. The key to avoiding the many complications arising from chromatic aberrations is to use low spatial frequency (<5 c/deg) sinusoidal gratings and to restrict the number of cycles visible. There is another good reason to use low spatial frequencies: the chromatic visual system is tuned to these, showing a low-pass tuning curve with a half-height of about 3 c/deg and an upper limit of about 10 c/deg [10]. The issue of stimulus size becomes particularly important when blue-yellow stimuli are used. This is because the central retina contains a higher concentration of yellow

Visual Evoked Potentials, Fig. 6 (Left) Occipital VEPs recorded to a range of chromatic axes, where 0/180 is cardinal red-green and 90/270 is cardinal blue-yellow

(see Fig. 5). (Below) Latency of the chromatic negativity as a function of chromatic axis

macular pigment, meaning that it is not possible to set a single value of isoluminance across the whole stimulus [11, 12]. Isoluminance also varies from subject to subject, even in those with normal color vision, largely because of the high inter-subject variability in the proportion of long-wavelength to medium-wavelength photoreceptors [► [Cone Fundamentals](#)]. Thus it is always advisable to establish isoluminance for each subject tested. The presence of color vision deficiencies is also important of course. In extremis, dichromatic individuals lack red-green opponency [Color Vision, Opponent Theory], and therefore do not generate red-green chromatic evoked potentials (see [Uses](#), below).

Uses

What benefits do chromatic VEPs bring, aside from giving us a tool to help understand the visual system? VEPs are useful in assessing the vision of preverbal individuals, and several studies have used VEPs to study the development of color vision in infants [13, 14]. There are many potential clinical uses, from the diagnosis of color vision deficiencies to the assessment of drug toxicity [15–18]. Studies have applied the technique to measure the effect of environmental toxins, which might be expected to preferentially affect the highly sensitive color visual system [► [Color Perception and Environmentally Based Impairments](#)]. The chromatic VEP has proven to be of value in neuro-ophthalmology [19–24], again because diseases such as optic neuritis seem to produce defective color vision. This may not be because the disease specifically targets color vision (for instance via the parvocellular pathway), but because the chromatic system is simply more sensitive to insult or injury, showing their effects more readily than the more robust achromatic visual system.

Definition

The *Vora Value*, ν , measures the recording accuracy of a set of color filters [1]. The definition of ν takes into account the viewing and recording illuminants and the target color space. The original definition is independent of the data set to be recorded, does not take into account recording

noise, and is based on the Euclidean distance measure in the target color space.

Let $\mathbf{V} = [\mathbf{v}_1 \mathbf{v}_2 \dots \mathbf{v}_s]$ be an $N \times s$ matrix whose columns are the vectors (or functions) that define the target color space for a specified viewing illuminant. If we assume that the vectors of $\mathbf{V}$ are independent, then they define a basis for the span of $\mathbf{V}$, $\text{Span}(\{\mathbf{v}_i\}_{i=1}^s)$. To simplify notation, we denote the span of $\mathbf{V}$ by $\mathbf{R}_s(\mathbf{V})$, where the subscript denotes the dimension of the vector space. For example, $\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3$ could represent the three *CIE XYZ* matching functions for viewing illuminant D65. Let the column vector $\mathbf{f}$ of length N represent the reflectance spectrum of the sample to be measured. Then the target color space is $\mathbf{R}_s(\mathbf{V})$, and the desired s -stimulus vector is

$$\mathbf{t} = \mathbf{V}^T \mathbf{f}$$

In our example, $\mathbf{t}$ would represent the *CIE XYZ* values of $\mathbf{f}$ for viewing illuminant D-65. The value of s need not be restricted to $s = 3$. For example, one may use $s = 6$ to measure the *CIE XYZ* values of $\mathbf{f}$ for viewing illuminants D-50 and D-65. For another example, $s = 4$ may be used to aid in color correction. For hyperspectral cameras and other multiband image recording systems, s may take on other, larger, values.

Let $\mathbf{M} = [\mathbf{m}_1 \mathbf{m}_2 \dots \mathbf{m}_r]$ be an $N \times r$ matrix whose columns represent the effective recording filters (combination of the scanning filters and scanning illuminant). If recording noise can be ignored, the vector of recorded values is

$$\mathbf{g} = \mathbf{M}^T \mathbf{f}$$

It is typically physically impossible – or, at least, impractical – to construct vectors $\mathbf{m}_i = \mathbf{v}_i$ that match the ideal color matching functions exactly. Further, recording and viewing illuminants generally differ. In general, $r \neq s$, $\mathbf{M} \neq \mathbf{V}$, and $\mathbf{t} \neq \mathbf{g}$. The vector $\mathbf{g}$ is typically color corrected to obtain the best linear estimate of $\mathbf{t}$, $\mathbf{t}_{\text{est}} = \mathbf{A}\mathbf{g}$, where color correction matrix $\mathbf{A}$ is chosen so as to minimize the mean square estimation error, $E\{\|\mathbf{t} - \mathbf{t}_{\text{est}}\|^2\}$, where $E\{\cdot\}$ is the expected value operator. If the components of $\mathbf{f}$ are assumed to be

independent, identically distributed with variance σ^2 , it can be shown that

$$\mathbf{A} = \mathbf{V}^T \mathbf{M} (\mathbf{M}^T \mathbf{M})^{-1}$$

and

$$E\{\|\mathbf{t} - \mathbf{t}_{\text{est}}\|^2\} = \sigma^2 \text{Trace}(\mathbf{V}^T \mathbf{V} - \mathbf{V}^T \mathbf{M} (\mathbf{M}^T \mathbf{M})^{-1} \mathbf{M}^T \mathbf{V})$$

The maximum value of $E\{\|\mathbf{t} - \mathbf{t}_{\text{est}}\|^2\}$ is $\sigma^2 \text{Trace}(\mathbf{V}^T \mathbf{V})$.

The Vora Value, ν , is a measure of the effectiveness of the set of recording filters $\{\mathbf{m}_i\}_{i=1}^r$, in recording the color of a sample in the target color space, $\mathbf{R}_s(\mathbf{V})$. It measures how accurately $\mathbf{t}$ can be estimated from $\mathbf{g}$ after linear color correction and is defined as

$$\nu = \left(\sigma^2 \text{Trace}(\mathbf{V}^T \mathbf{V}) - E\{\|\mathbf{t} - \mathbf{t}_{\text{est}}\|^2\} \right) / \sigma^2 \text{Trace}(\mathbf{V}^T \mathbf{V})$$

Note that ν increases linearly with a decrease in mean square estimation error and ranges in value from zero to one, where the maximum value of one corresponds to perfect recording.

The definition of ν does not take into account recording noise, real data sets, or perceptual error measures, each of which would influence the error expression. For measures that take these into account, please see the section on *Other Measures* below. The original form of ν is simple and provides an effective rough estimate of the accuracy of the filter set.

Motivation: The Measure ν and the Q-Factor

To understand the properties of a good filter set, note that $\mathbf{t}$ consists of the inner products (dot products) of the vectors $\mathbf{v}_1 \mathbf{v}_2 \dots \mathbf{v}_s$ with the vector $\mathbf{f}$ [2]. Thus $\mathbf{t}$ depends only on the *fundamental* of $\mathbf{f}$, which is defined as $\mathbf{P}_V(\mathbf{f})$, its orthogonal projection onto the target color space. On the other hand, any components of $\mathbf{f}$ that are orthogonal to all of

$\mathbf{v}_1 \mathbf{v}_2 \dots \mathbf{v}_s$ will not contribute to $\mathbf{t}$. Thus, in particular, $\mathbf{f} - \mathbf{P}_V(\mathbf{f})$ does not contribute to $\mathbf{t}$.

$$\mathbf{t} = \mathbf{V}^T \mathbf{f} = \mathbf{V}^T \mathbf{P}_V(\mathbf{f}) + \mathbf{V}^T (\mathbf{f} - \mathbf{P}_V(\mathbf{f})) = \mathbf{V}^T \mathbf{P}_V(\mathbf{f}) + \mathbf{0}$$

Figure 1a illustrates this for $s = 2$. Vectors $\mathbf{v}_1$ and $\mathbf{v}_2$ define the target color space, the horizontal plane. The reflectance spectrum is represented by three-dimensional vector $\mathbf{f}$. The vector $\mathbf{t}$ is completely determined by $\mathbf{P}_V(\mathbf{f})$, the orthogonal projection of $\mathbf{f}$ onto the horizontal plane. The inner product of $\mathbf{f} - \mathbf{P}_V(\mathbf{f})$ with either of $\mathbf{v}_1$ or $\mathbf{v}_2$ is zero and hence does not contribute to $\mathbf{t}$.

Let $\mathbf{m}$ represent a single effective recording filter, obtained by combining the filter transmission function and the recording illuminant. Ignoring recording noise, the value $\mathbf{m}^T \mathbf{f}$ or the inner product of vectors $\mathbf{m}$ and $\mathbf{f}$ is the recorded value. The component of $\mathbf{m}$ that is orthogonal to the target color space, $\mathbf{m} - \mathbf{P}_V(\mathbf{m})$, contributes to inaccuracy in the recording of $\mathbf{t}$ because it measures energy in $\mathbf{f} - \mathbf{P}_V(\mathbf{f})$. This is illustrated in Fig. 1b.

$$\begin{aligned} g = \mathbf{m}^T \mathbf{f} &= \left(\mathbf{P}_V(\mathbf{m})^T + (\mathbf{m} - \mathbf{P}_V(\mathbf{m}))^T \right) \\ &\quad (\mathbf{P}_V(\mathbf{f}) + (\mathbf{f} - \mathbf{P}_V(\mathbf{f}))) \\ &= \mathbf{P}_V(\mathbf{m})^T \mathbf{P}_V(\mathbf{f}) \\ &\quad + (\mathbf{m} - \mathbf{P}_V(\mathbf{m}))^T (\mathbf{f} - \mathbf{P}_V(\mathbf{f})) \end{aligned}$$

Thus we have seen that only the fundamental of $\mathbf{m}$, $\mathbf{P}_V(\mathbf{m})$ is useful for recording accuracy. The

Colorimetric Quality Factor (CQF or q-factor, defined by Neugebauer in 1956) of $\mathbf{m}$ measures the accuracy of $\mathbf{m}$ from this perspective, and is defined as the energy in the vector $\mathbf{P}_V(\mathbf{m})$, as a fraction of the total energy in $\mathbf{m}$.

$$q(\mathbf{m}) = \|\mathbf{P}_V(\mathbf{m})\|^2 / \|\mathbf{m}\|^2$$

The value of $q(\mathbf{m})$ is larger when $\mathbf{P}_V(\mathbf{m})$ is a larger fraction of $\mathbf{m}$. If $\mathbf{m} \in \mathbf{R}_s(\mathbf{V})$, $\mathbf{P}_V(\mathbf{m}) = \mathbf{m}$, and $\mathbf{m}$ has a maximum q-factor of one.

While the CQF captures an important requirement of color scanning filters, recording filters are not used by themselves and it is necessary to evaluate filter sets as opposed to single filters. As in the case of a single filter, it is important for the filter set to measure the energy in $\mathbf{P}_V(\mathbf{f})$. Thus the approach underlying the q-factor is useful. However, while a single filter can record energy only in one “direction” of the target color space (e.g., a single filter can measure one of the CIE tristimulus values) the purpose of a filter set is to measure energy in all the directions of the target color space. Thus, for example, if we wish to record CIEXYZ tristimulus values, the filter set should accurately measure X, Y, and Z values. An evaluation criterion for a set of recording filters should hence evaluate whether it measures all the energy in $\mathbf{P}_V(\mathbf{f})$ — that is, whether it measures the energy in $\mathbf{P}_V(\mathbf{f})$ in all directions of the target color space.

The generalization of the q-factor to the evaluation of a filter set is not trivial. To see this,

Vora Value, Fig. 1 (a) $\mathbf{f} - \mathbf{P}_V(\mathbf{f})$ does not contribute to $\mathbf{t}$. (b) $\mathbf{m} - \mathbf{P}_V(\mathbf{m})$ measures parts of $\mathbf{f} - \mathbf{P}_V(\mathbf{f})$

consider, for example, a set of three perfect red filters, each with a q-factor of one. While these are clearly inadequate to measure tristimulus values, *any* function of individual q-factors will indicate that the set is perfect. This limitation is illustrated in Fig. 2a for $s = 2$. The two filters $\mathbf{m}_1$ and $\mathbf{m}_2$ are both perfect, lie in $\mathbf{R}_r(\mathbf{M})$ and have q-factors of 1. However, one is a multiple of the other. Hence the filter set is not capable of measuring that part of $\mathbf{P}_V(\mathbf{f})$ that is orthogonal to the filters. It is hence not capable of measuring all the energy in $\mathbf{P}_V(\mathbf{f})$.

The general case is illustrated for $s = r = 2$ in Fig. 2a. The two recording filters $\mathbf{m}_1$ and $\mathbf{m}_2$ do not lie in the target color space, which is the horizontal plane, but in the shaded plane. The desired recorded values depend on $\mathbf{P}_V(\mathbf{f})$. The values that are recorded in practice depend on $\mathbf{P}_M(\mathbf{f})$.

$$\begin{aligned} \mathbf{g} &= \mathbf{M}^T \mathbf{f} = \mathbf{M}^T \mathbf{P}_M(\mathbf{f}) + \mathbf{M}^T (\mathbf{f} - \mathbf{P}_M(\mathbf{f})) \\ &= \mathbf{M}^T \mathbf{P}_M(\mathbf{f}) + \mathbf{0} \end{aligned}$$

Hence the set of filters is perfect when $\mathbf{R}_r(\mathbf{M}) = \mathbf{R}_s(\mathbf{V})$, and the error is not dependent on individual filters but on the spaces. Thus $E\{\|\mathbf{t} - \mathbf{t}_{est}\|^2\}$ depends on how much of the energy of $\mathbf{R}_r(\mathbf{M})$ is contained in $\mathbf{R}_s(\mathbf{V})$, or, equivalently, how much of the energy of orthogonal filters spanning $\mathbf{R}_r(\mathbf{M})$ is contained in $\mathbf{R}_r(\mathbf{V})$. It may be shown that

$$v(\mathbf{V}, \mathbf{M}) = \sum_{i=1}^r \frac{q(\mathbf{o}_i)}{s},$$

where $\{\mathbf{o}_i\}_{i=1}^r$ is an orthogonal basis for $\mathbf{R}_r(\mathbf{M})$ and $q(\mathbf{o}_i)$ is the q-factor of $\mathbf{o}_i$. The use of orthogonal filters prevents correlation among filters from artificially increasing the value of the measure (as in Fig. 2a).

Additional insight into the power of the Vora Value is obtained by considering the case where the target space is the horizontal plane in 3-space. A set of three independent vectors, none of which lie in the plane, form a basis of the 3-space. None of the vectors will have a q-factor of one. It is clear that the span of the three vectors includes the target space. For this case, $v = 1$, as it should. Thus, we can create a filter set that produces perfect tristimulus values from imperfect filters. The cost of this is that it requires more filters than the dimension of the target color space, i.e., $r > s$.

The Measure v and Principal Angles

It may be shown that

$$v(\mathbf{V}, \mathbf{M}) = \sum_{i=1}^s \frac{\cos^2(\theta_i)}{s}$$

where θ_i is the i^{th} principal angle [3] between the target color space, $\mathbf{R}_s(\mathbf{V})$, and $\mathbf{R}_r(\mathbf{M})$.

Vora Value, Fig. 2 (a) *Left*: Two or more scanning filters should not record energy in a single direction. (b) *Right*: Differences between $\mathbf{R}_r(\mathbf{M})$ and $\mathbf{R}_s(\mathbf{V})$ lead to inaccurate recording

Other Measures

The measure v is based on a mean-square error in the target color space assuming independent, identically distributed data. It does not take into account real data sets, perceptual error, or recording noise.

Finlayson and Drew [4, 5] address the issue of real data sets. They propose a similar measure based on the *White Point Preserving Vora Error With Maximum Ignorance With Positivity (WPPVEMIP)*, which assumes that one is maximally ignorant of the distribution of $\mathbf{f}$ except for knowing that all values in the vector $\mathbf{f}$ are positive and that the color correction procedure preserves white points. They demonstrate that the *WPPVEMIP* is a more accurate estimate of the real error, and hence that the corresponding measure is more accurate than v .

Wolski et al. [6] address the issue of perceptual error by using a linear approximation of CIE Lab error in the neighborhood of the points in the (known) data set. The filter sets designed by this method minimize an error measure that is a better estimate of perceptual error than the mean square error used to define v .

Sharma and Trussell [7] address the issue of recording noise and propose a *Figure of Merit (FOM)* based on the approach of Wolski et al.

The FOM is derived from an error that takes into consideration recording noise.

World Color Survey

Paul Kay and Richard S. Cook
Department of Linguistics, University of
California, Berkeley, CA, USA

Definition

The World Color Survey collected comprehensive color-naming data from an average of 24 speakers

of each of 110 unwritten languages from around the world. Analysis of these data has resulted in a number of research publications. The data are available at <http://www1.icsi.berkeley.edu/wcs/data.html>.

Introduction

The World Color Survey (WCS) was undertaken to investigate the main findings of Berlin and Kay (B&K) [1]. These were (A) that there exist universal crosslinguistic constraints on color naming and (B) that basic color terminology systems tend to develop in a partially fixed order. To this end, the WCS collected color-naming data from speakers of 110 unwritten languages. The WCS data are available in the WCS Data Archive. This entry reviews the history of the WCS, including the creation of the online data archive, and describes some recent uses of the archive to investigate constraints on color naming across languages.

The WCS: History and Methodology

The WCS was begun in 1976 to evaluate the findings of B&K in a full-scale field study. B&K had investigated the color terminology systems of 20 languages in the following way. The stimulus palette used by Erik Lenneberg and John Roberts [2], consisting of 320 Munsell chips of 40 equally

World Color Survey, Fig. 1 (a) The WCS stimulus palette. (b) Munsell and WCS coordinates for stimulus palette of (a). The leftmost column and the top row give the WCS coordinates for lightness and hue, respectively. The rightmost column and the bottom two rows give the

Munsell coordinates for value and hue, respectively. Entries in the body of the table show the corresponding Munsell chroma numbers. (With regard to the A and J rows, there are no Munsell hues at the extremes of value (lightness): 9.5 (*white*) and 1.5 (*black*))

spaced hues and eight levels of lightness (value) at maximum saturation (chroma) for each (hue, value) pair, was supplemented by nine Munsell achromatic chips (black through gray to white) – an approximation of the resulting stimulus palette is shown in Fig. 1a and the corresponding Munsell coordinates in Fig. 1b.

First, without the stimulus palette present, the major color terms of the collaborator’s native language were elicited by questioning that was designed to find the smallest number of simple words with which the speaker could name any color (*basic color terms*). Once this set of terms was established, the collaborator was asked to perform two tasks. In the *naming* task the stimulus palette was placed before the speaker, and for each color term *t*, a piece of clear acetate was placed over the stimulus board, and the collaborator was asked to indicate, with a grease pencil on the acetate sheet, all the chips that he or she could call *t*. In the *focus* task the stimulus palette was shown as before, and the collaborator was asked

to indicate the best example(s) of *t* for each basic color term *t*. B&K concluded that

[1] The referents for the basic color terms of all languages appear to be drawn from a set of eleven universal perceptual categories, and [2] these categories become encoded in the history of a given language in a partially fixed order. [1]

The original universal evolutionary sequence of color term development postulated by B&K is shown in Fig. 2. It has subsequently been revised in detail as more data has become available, but the main outlines of the original sequence have remained intact (see Fig. 3, for the most recent revision).

The B&K results were immediately challenged by anthropologists on the grounds that the sample of experimental languages was too small, too few collaborators per language were questioned (sometimes only one), all native collaborators also spoke English, the data were collected in the San Francisco Bay area rather than in the homelands of the target languages, many regions of the

development

world and language families were underrepresented or overrepresented in the sample of 20, and that the sample of 20 had too few unwritten languages of low technology cultures [3–6]. The results were nevertheless supported by various ethnographic and experimental studies conducted after 1969 and were from the start largely accepted by psychologists and vision researchers (e.g., [7–9]. See also [10], 498ff, [11], 133 ff).

Work on the WCS was begun in the late 1970s. Through the cooperation of SIL International (then the Summer Institute of Linguistics), which maintains a network of linguist-missionaries around the world, data on the basic color term systems of speakers of 110 unwritten languages representing 45 different families and several major linguistic stocks were gathered in

situ. Fieldworkers were provided with a kit containing the stimulus materials (330 individual chips in glass 35-mm slide sleeves for the naming task and the full stimulus palette for the focus task) as well as coding sheets on which to record collaborators’ responses. The included instructions requested that fieldworkers collect data from at least 25 speakers, both males and females, and urged them to seek out monolingual speakers insofar as possible. The modal number of speakers actually assessed per language was 25, and the average number was 24. (A facsimile of the WCS instructions to fieldworkers and of the original coding sheets is available on the WCS website.) The aim was to obtain names, category extent, and best examples of basic color terms in each language – basic color terms being described in the instructions as “the smallest set of simple

words with which the speaker can name any color.”

The WCS methodology coincided with that of the B&K study in the use of essentially the same set of Munsell color chips. One white chip was added in the WCS study that was whiter than any chip available at the time of the B&K study, making for a total of ten achromatic chips and an overall total of 330 chips, as shown in Fig. 1.

The WCS differed from B&K in the technique for eliciting naming responses. In the WCS procedure, no preliminary interview was administered to establish a set of basic color terms, and in the naming task the 330 individual color stimuli were shown to each cooperating speaker, one by one, according to a fixed, pseudorandom order, and a name elicited for each (in contrast with the B&K procedure of presenting the entire stimulus palette at once in eliciting naming responses). Fieldworkers were instructed to urge observers to respond with short names (although, depending on the morphology of the language, particular field circumstances, and local culture, there was considerable variation in the degree to which the field investigators were able to satisfy these desiderata). Identification of basic color terms, therefore, was done by the fieldworker as a result of the naming task itself, rather than through prior elicitation. The best example (focus) responses were elicited in the same way in both studies: once a set of basic color terms was isolated, the native observer was presented with the full palette and asked to indicate the chip or chips that represented the best example of each term, one by one.

Initial Analysis

Originally, the naming and best example data of the WCS were entered into separate files for each language; they were not compiled into a unified database until the early 2000s. In 2009, a monograph [13] appeared, based on analysis of data in this form. It contains a separate chapter for the color-naming system of each language, identifying the basic terms of the language through a variety of ways of summarizing and displaying the data. An updated version of the original B&K evolutionary sequence was postulated and is depicted in Fig. 3.

Uses of the WCS Archive

The WCS data archive has been used in investigating two broad questions, one concerning *universals* and other concerning *variation*, of color naming, corresponding to the two major conclusions of B&K [1]. Numerous statistical studies utilizing the WCS online have been conducted.

Universals of Color Naming

Since B&K found evidence for universals in color naming across languages, the existence of such constraints has generally been accepted in the scientific community. However, there have always been dissenters from this consensus (e.g., [2, 3]), and this dissenting view has recently gained prominence (e.g., [14–19]). Criticisms of the universalist position have come in two major varieties. The first points out that B&K’s findings were never objectively tested, as they relied on visual inspection of color-naming data. Lucy [15] challenges such a methodology as hopelessly subjective:

[Work in the B&K tradition] not only seeks universals, but sets up a procedure which guarantees both their discovery and their form. . . . when a category is identified . . . it is really the investigator who decides which ‘color’ it will count as . . . What appears to be objective - in this case, a statement of statistical odds - is [not]. ([15], p. 334)

On this view, B&K’s subjective methodology allowed them to impose their own universalistic assumptions on their data – so the universals are actually in the minds of the investigators, not in the languages of the world. The second strand of criticism points out that B&K’s data were drawn primarily from written languages and thus may not be representative. This point is coupled with analyses of particular unwritten languages, which are claimed to counterexemplify universal constraints (e.g., Berinmo: [18, 19]; Hanunóo and Zuni: [15]). Subsequent, more detailed analyses of each of these languages have found that each fits the universal pattern [20]. Disputes of this sort over conflicting interpretations of individual color-naming systems could continue indefinitely.

Objective statistical studies were needed to resolve the issue.

The WCS database has been used in a number of independent statistical studies to test the hypothesis that there are statistical constraints on the basic color-naming systems of languages. The weight of the evidence supports the conclusion that such universal statistical constraints exist. The centroids of the naming responses to all color categories documented in the survey were found to cluster in color space more closely than chance would dictate; in a Monte Carlo simulation of the WCS, in which on each of 1,000 trials the modal color-naming pattern of every WCS language was rotated a random hue angle, the actual WCS naming centroids were found to cluster more tightly than the naming centroids in any of the 1,000 hypothetical (rotated) versions of the WCSs [21]. Figure 4 presents a contour plot of the WCS naming centroids compared to those of English.

The best example choices (foci) of all WCS color terms were found to also cluster more tightly than the centroids of naming categories, suggesting an intimate relation between “focal” colors and universal tendencies of color naming [23]; further, the WCS focal choices were found to cluster closely to those of English or other familiar written languages, as shown in Fig. 5.

Whereas the studies just discussed relied on color naming and focus choice data grouped by language, a clustering and concordance study based on the naming patterns of individual participants independently supports the conclusion that the WCS languages largely partition the color space in ways that, although often having fewer basic terms than English and hence fewer boundaries in their lexical “map” of color space, tend strongly to place boundaries in the same locations as do English and other familiar written languages [24]. This study also detected a hierarchical order in the lexical partitions of color space compatible with that depicted in Fig. 3. The question naturally arises regarding the degree to which WCS “focus” judgments, that is, participants’ judgments of the most typical examples of named categories, will agree with judgments of unique hues. For example, to what extent do people’s judgments of the best example of green agree with their (actually, in this case, with other people’s) judgments of a green that contains neither blue nor yellow. In a study that pruned the WCS data to consider 38 languages that yield unequivocal results for the Hering fundamental hues, red, yellow, green, and blue, it was found that the focal judgments of the WCS participant speakers of unwritten languages agreed well with unique hue judgments of 300 speakers of several written languages [25].

World Color Survey, Fig. 4 Contour plot of WCS speakers’ naming centroids, compared with English naming centroids (*black dots*); source for English naming centroids: [22]. The outermost contour represents a height of

100 centroids, and each subsequent contour represents an increment in height of 100 centroids (Source of figure: [21])

World Color Survey,

Fig. 5 Contour plot of focal color responses from WCS languages, with superimposed focal responses from English (B&K data, shown as dots), plotted against the stimulus palette (Source: [23])

Systematic, statistical comparison with the WCS database of languages claimed to violate universal color-naming tendencies has refuted that claim; however, a small number of other languages, not the object of such claims, have in fact been found to violate universal tendencies [26]. In a different study, languages with terms roughly equivalent to red, yellow, green, and blue nevertheless were found to differ slightly in their average focus placements, although this variation was greatly exceeded by that found among speakers of the same language [27]. A tentative explanation of the universal tendencies in color naming was found in a study that modeled hypothetical color-naming systems minimizing within-category distance in color space; good fit between the data generated by this model and the WCS data was achieved [28]. One explanation for variation across speakers within a given language is that there appear to be a small number of patterns of naming that occur among some speakers of many languages, with the speakers of few languages all following the same naming pattern [29]. Analysis of the WCS database has revealed that the categories named by basic color terms in the world's languages tend to be convex sets in color space [30]. An iterated learning study in which a stable color-naming system is achieved by interacting hypothetical agent has shown that equipping such hypothetical agents with the human just noticeable difference function at the start is sufficient to produce a final output that matches the WCS data well [31]. An iterated learning study using actual human learners showed that limiting a given simulation to just the number of color terms also produced systems

of color naming that were statistically close to corresponding systems in the WCS [32]. Extensive narrative descriptions of the color-naming systems of each WCS language, supported by charts and tables and keyed to the overall universal classification scheme, are available in monograph form [13].

Wright, David

Robert W. G. Hunt

Department of Colour Science, University of
Leeds, Leeds, UK

W. David Wright was a British physicist and color scientist who made very important contributions to colorimetry and visual science. In fact he is generally regarded as one of the fathers of colorimetry as it is practiced today.

Wright graduated at Imperial College, London University, in 1926 and received a Ph.D. in 1929 and a D.Sc. in 1937. He was a Medical Research Council student at Imperial College from 1926 to 1929, and in this period, the spectral color-matching properties of ten observers were measured.

He was a Research Engineer at Westinghouse Electric and Manufacturing Co., Pittsburgh, USA, in 1929–30, where he undertook early research on color television.

On his return to England, at Imperial College, he became a Lecturer and Reader in Technical Optics in 1930–1951 and Professor of Applied Optics in 1951–1973. He was a Research and Consultant Physicist to Electrical and Musical Industries in 1930–1939. He became Kern Professor of Communications at the Rochester Institute of Technology in 1984–1985.

Main Interests

W. David Wright had a number of interests which included optics, vision, photometry, colorimetry, color perception, color applications, and color paintings. He supervised a succession of research students in color science, many of whom subsequently held senior positions in academia and industry.

Wright's most important research work was the measurement, for ten observers, of the way in which the colors of the spectrum are matched by beams of red, green, and blue light added together. This work, together with a similar study carried out by John Guild (at the National Physical Laboratory at Teddington, England, with seven additional observers), forms the basis of the international standard for measuring color established by the Commission Internationale de l'Éclairage (CIE). The quality of this experimental work was so high that the standard, although now more than eighty years old, is still in universal use.

Wright's researches also led, for the first time, to definitive descriptions of the main types of color deficiency (color blindness). His book *Researches on Normal and Defective Colour Vision*, published in 1946, summarizes the results of his research on color vision. He also wrote the book *The Measurement of Colour*, the four editions of which provided a widely used practical guide to colorimetry from 1944 to the present time. His leisure interests included an appreciation of paintings and religious service and church activities.

Wright's books and key publications include:

The Perception of Light, Blackie, 1938.
Researches on Normal and Defective Colour Vision, Kimpton, 1946.
The Measurement of Colour, Hilger, 1944 (2nd ed., 1958; 3rd ed., 1964; 4th ed., 1969).
Photometry and the Eye, Hatton, 1950.
The Rays are not Coloured, Hilger, 1967.

He also authored about 80 original papers, mainly dealing with color and vision.

Wright received numerous awards and was a member of several professional bodies which included:

The Physical Society Thomas Young Oration, 1951.
 Honorary D.Sc. City University, 1971.
 The AIC (International Colour Association) Judd Award, 1977.
 Honorary D.Sc. University of Waterloo, Canada, 1991.

He also provided public and professional service which included:

Founder of the Physical Society Colour Group, 1941.
 Chairman of the Physical Society Colour Group, 1941–1943.
 Vice-President of the Physical Society, 1948–1950.
 Secretary of the International Commission for Optics, 1953–1966.

Chairman of the Physical Society Optical Group, 1956–1959.
 President of the International Colour Association (AIC), 1967–1969.
 Chairman of the Colour Group (Great Britain), 1973–1975.

Wyszecki, Gunter

Rolf G. Kuehni
 Charlotte, NC, USA

Biography

Gunter Wyszecki was a German-Canadian mathematician/physicist who made important contributions to the fields of colorimetry, color discrimination, color order, and color vision [1]. He was born in Tilsit, East Prussia, Germany (today Sovetsk, Russia), in 1925. He attended the Technische Universität Berlin where he obtained a Dr.-Ing. degree, with a dissertation on normal and anomalous trichromacy [2]. In 1953 he was awarded a Fulbright Scholarship and for a year joined Deane B. Judd at the Colorimetry and Photometry Section of the US National Bureau of Standards in Washington, DC. In 1955 Wyszecki joined the National Research Council Canada in Ottawa where he became the leader of its Optics

Section in 1960 and assistant director of the Division of Physics in 1982 and where he remained until his untimely death from leukemia on June 22, 1985.

Major Accomplishments/Contributions

Wyszecki is best known for his scientific contributions to and leadership in the International Commission on Illumination (CIE). He was chairman of its Colorimetry Committee from 1963 to 1975, vice president of the organization from 1979 to 1983, and its president from 1983 until his death. During this period the CIE made many important recommendations in colorimetry, remaining valid today, such as 1 nm tables of the color-matching functions of the two CIE standard observers and the standard illuminants A and D65, addition of integrating sphere reflectance factor measurement as a recommended measuring geometry, the 1964 ($U^*V^*W^*$) and the 1976 CIELAB and CIELUV uniform color space and color-difference formulas, and others.

Metamerism Wyszecki introduced the important mathematical concept of “metameric blacks,” psychophysical definitions of blacks with tristimulus values 0, 0, 0 that, within limits, can be added to a spectral reflectance to form the various possible metamers having an identical set of tristimulus values under a given light [3]. With W.S. Stiles he also developed mathematical methods to calculate by various methodologies the number of possible metamers for given chromaticities, peaking at the achromatic colors [4].

Wyszecki seven-field colorimeter In 1965 Wyszecki developed the seven-field colorimeter with which an observer can view with both eyes one or more of seven hexagonal fields, each with separately controllable RGB sources, achieved with filtered light and mixed in an integrating sphere. It was successfully used in many different research projects.

Color matching and color-difference matching The MacAdam color-matching error ellipses of 1942 (1 observer) were extended in 1957 to 12 observers by Brown. In 1971 Wyszecki and Fielder determined color-matching error

ellipsoids for three observers [5]. The latter two investigations demonstrated the considerable variability by observer. The seven-field colorimeter was also used for a novel color-difference matching experiment in which three fields were displayed and the observer had to adjust the third field so that its brightness matched the brightness of preselected colors with equal luminance in two fields and its chromaticity resulted in identical perceived differences between the colors in the triangular arrangement [6].

Heterochromatic brightness matching
Wyszecki and coworkers added important experimental data to the luminance of equally bright-appearing stimuli. Many chromatic stimuli, when compared to achromatic ones of the same luminance or luminous reflectance, appear to be lighter or brighter, to be “glowing,” an effect known as the Helmholtz-Kohlrausch effect [7].

Publications Wyszecki authored or coauthored 86 scientific papers and 3 books. The first book, *Farbsysteme*, was published in Germany in 1960 [8], describing various color order systems. He coauthored together with D. B. Judd the second and third editions of the latter's *Color in Business, Science, and Industry*, the third edition published after the passing of Judd [9]. He was the lead author, together with W. S. Stiles, of the monumental *Color Science: Concepts and Methods*,

Quantitative Data and Formulae, with editions in 1967 and 1982 [10]. The second edition remains in print today as a highly important source of information in the field of color science.

Xenon Lamp

Wout van Bommel
van Bommel Lighting Consultant, Nuenen,
The Netherlands

Definition

Lamps that produce light as a result of an electrical discharge, generated between two electrodes, in a high-pressure pure xenon gas, which is contained in a transparent bulb.

Note: So-called xenon gas discharge lamps for automobile lighting are in fact metal halide gas discharge lamps in which xenon gas does not contribute to the radiation but is added solely to facilitate ignition of the lamp. These lamps do not belong to the category of pure xenon lamps and are therefore not described here.

Short-Arc Xenon Lamps (Fig. 1)

The light-emitting surface of short-arc xenon lamps is a near-point source of very high luminance with excellent and constant color properties. They are developed as an energy-efficient and safe substitute for the awkward and flammable carbon arc lamps used until the 1960s in movie projectors in cinemas. The first movie projection using a short-arc xenon lamp was demonstrated in

1950 in West Berlin by OSRAM. Today's short-arc xenon gas discharge lamps are used for cinema movie projection, film and studio lighting, followspots in theater lighting, searchlights, and lighthouses. Smaller types are used in microscopy, spectroscopy, and optical measurements. The spectrum resembles that of a black body radiator of 6300 K and is very similar to the sun's spectrum.

Long-Arc Lamps (Fig. 2)

Xenon lamps with a larger distance between the electrodes are used in elliptical projector type of sun simulators. They are used for age testing of devices (including solar cells), rapid thermal processing, and material inspection. Versions that deliver short flashes of light are used for photography and industrial applications. They avoid heat build-up in the devices being tested. Their spectrum resembles, just like the short-arc xenon lamp's spectrum, that of a black body radiator of 6300 K, similar to the spectrum of the sun. Where the simulator needs to have a luminance approaching that of the sun's surface, short-arc lamps are employed.

Long-arc xenon lamps were introduced in the late 1950s as an alternative for incandescent lamps in stadium floodlighting. For lighting purposes, these large lamps have since the 1960s been completely superseded by metal halide lamps which have a much higher efficacy.

Xenon Lamp, Fig. 1 Short-arc xenon lamp. (Photograph: Signify)

Xenon Lamp, Fig. 2 Long-arc xenon lamp of the flash type

Working Principle and Construction

Short-arc xenon lamps exist of a single, double-ended, discharge tube of quartz with two electrodes of solid tungsten (Fig. 1). The cathode is cone-shaped with a sharp tip and doped with thorium oxide to facilitate electron emission. Light emission takes place in a very tiny cloud of xenon gas where the electrons leave the cathode tip. The anode is bombarded by the electrons and becomes very hot. It is flat-shaped, large, and of heavy construction to facilitate heat dissipation and increase life. The high-power version lamps need either forced air or water cooling. The very short electrode gap between cathode and anode varies, per type, between some 0.5 and 15 mm. The cone-shaped arc discharge stretches from cathode to anode and is consequently very small and of very high luminance. In vertical burning position, the arc exactly lines up with the electrodes. In horizontal burning position, convection forces may lift up the arc, and a magnet (a current through a coil) is in some types required for a stable, lined up arc position. The very high operating pressure of 10–50 atmospheres requires a cold pressure of some 3–15 atmospheres. During the manufacturing process, therefore, xenon is brought into the discharge tube in frozen form.

Short-arc xenon lamps must be operated on DC power because the very high arc currents require a

different construction of the cathode and anode as described above. The high cold pressure requires high starting voltage peaks up to 50 kV; some types are therefore equipped with an auxiliary electrode to facilitate ignition.

Long-arc xenon lamps have a similar construction as the short-arc versions, but the electrodes are at a larger distance from each other. The light-emitting area of the lamp is longitudinal along the length of the tube.

Properties

System Luminous Efficacy

System luminous efficacies are from 15 lm/W to 50 lm/W. The lower values correspond to lower wattage and lower electrode gap versions.

Lumen Package and Luminance Range

An extensive range of lumen packages is available, varying from some 1000 to more than 1 million lumen (corresponding to some 75–20,000 W). The arc luminance varies, depending on the wattage and electrode gap version, between roughly 20,000 and 500,000 cd/cm^2 (corresponding arc gap, 15–0.5 mm). The higher luminance value is the highest of all electric lamp types and is higher than the luminance of the surface of the sun of approximately 150,000 cd/cm^2 .

Color Characteristics

Contrary to most gas discharge lamps, the spectrum of a short-arc xenon lamp approaches that of a near-continuous spectrum and is practically independent of lamp type, wattage, dimming state, and operating hours. In the visible range, it resembles a black body radiator of 6300 K. The color rendering index is better than 90.

Outside the visible area, the lamps also produce ultraviolet radiation in the region down to 150 nm. The result is that ozone is produced during operation (ultraviolet radiation reacts with oxygen in the air resulting in ozone). In most applications, the oxidizing effect and smell of ozone are unwanted. To avoid these adverse effects, some lamp versions employ doped or coated quartz material that absorbs ultraviolet radiation with wavelengths smaller than 240 nm.

Lamp Life

Average lamp life varies with type from 500 h to 2500 h.

Run-Up and Reignition

Full light output is obtained almost instantaneously. Hot reignition is also immediate.

Handling

The cold pressure of 2–15 atmospheres requires precautions in lamp handling in order to prevent explosion. Protective coverings are supplied with the lamp for safe transportation and handling.
